To estimate the sugar in the blood.—Gardner and Maclean's modification of Bang's method is as follows: "Two or three drops of blood are soaked up in weighed pieces of filter paper 12 x 25 mm. in size and 1 mm. thick weighing about 100 mgm. and weighed. The weighing is most conveniently effected with a torsion balance. The paper containing the blood is placed for 3 to 5 minutes in an oven at 90° to 100° to coagulate the proteins. The glucose contained in the blood is extracted by immersing the paper in 7 c.c. of a solution containing 150 c.c. of saturated potassium chloride solution, 70 c.c. of water, and 2 to 3 drops of 40 per cent. acetic acid for 45 minutes to 1 hour, during which time it is raised twice to the boiling point. The solution is poured into a 50 c.c. Jena glass flask with a straight neck and no rim. The paper is again boiled out with 4 c.c. of the above solution in the same way and this is put into the flask. Three c.c. of the alkaline copper solution are added. The flask is closed with a piece of rubber tubing 3 mm. thick and 4 to 5 cm. long, leaving 2 cm. over, which can be clamped with a spring clip or a special clip. Dissolved gases are removed by shaking and exhausting the flask with a suction pump. The contents of the flask are heated to boiling for 3 minutes; just before the expiration of this time the tubing being closed with the cap. The flask is rapidly cooled under running water. The rubber cap is removed, and to prevent oxidation a current of carbon dioxide is immediately passed through the flask by a small tube which is bent for convenience and attached to the flask by a band. The reduced cuprous salt is titrated with .01N iodine solution or .005N iodine solution, which is prepared from .1N iodine solution contained in a 2 c.c burette with a fine point and graduated in fiftieths of a c.c. using 2 to 3 drops of starch solution as indicator. In all cases .01 per cent. should be subtracted from the final result, since blood contains a substance which reduces iodine.

"Gardner and Maclean state that at least four parallel determinations should be carried out and the mean of three or four satisfactory estimations taken as the correct figure." (Plimmer's *Organic and Bio-Chemistry.*)

MATERIA MEDICA.

1. Arsenic belongs to the indefinite class called "alteratives." It is found as the sulphide; also in combination with iron, nickel, or cobalt; a small amount is found free.

Official preparations, with their doses: Arseni trioxidum, gr. 1/30; Liquor acidi arsenosi, ♏iij; Arseni iodidum, gr. 1/12; Sodii arsenas, gr. 1/12; Sodii arsenas exsiccatus, gr. 1/20; Liquor potassii arsenitis, ♏iij; Liquor sodii arsenatis, ♏iij; Liquor arseni et hydrargyri iodidi, ♏j.

2. *Preparations and doses of ammonium:* Ammonia water ♏xv; carbonate of ammonia, gr. iv; aromatic spirit of ammonia, ♏xxx; ammonium chloride, gr. v; solution of ammonium acetate, ʒiv; ammonium benzoate, gr. xv; ammonium iodide, gr. iv; ammonium salicylate, gr. viij; ammonium valerate, gr. vij; solution of iron and ammonium acetate, ʒiv.

3. *Six preparations of sodium, with doses:* Sodium acetate, gr xv; sodium benzoate, gr. xv; sodium bicarbonate, gr. xv; sodium borate, gr. xij; sodium bromide, gr. xv; and sodium chloride, ʒiv.

4. *Nux vomica* is the dried, ripe seed of the strychnos nux vomica. It is of a grayish color, covered with thin hairs; internally it is whitish-gray, and is tough and horny. Its chief constituents are strychnine, brucine, igasuric acid, and loganin.

The official preparations and doses of nux vomica are: Nux vomica, one grain; extract of nux vomica, one-quarter of a grain; fluid extract of nux vomica, one minim; tincture of nux vomica, eight minims.

Two alkaloids of nux vomica: Strychnine, gr. 1/40; brucine, gr. 1/32 (not official).

5. *Opium* is the exudation obtained from incising the unripe capsules of the *Papaver somniferum* (white poppy); it should yield not less than 9 per cent. of crystallized morphine. It is chiefly obtained from Constantinople and Egypt.

Six preparations and doses: Deodorized opium, 1 grain; granulated opium, 1 grain; powder of ipecac and opium, 8 grains; tincture of opium, 8 minims; camphorated tincture of opium, 8 minims; tincture of deodorized opium, 8 minims. *The chief alkaloid of opium* is morphine.

6. *Six official preparations of iron, with their doses:* Reduced iron, 1 grain; ferrous sulphate, 1½ grains; pills of ferrous carbonate, 2 pills; tincture of ferric chloride, 8 minims; solution of iron and ammonium acetate, 4 drams; iron and quinine citrate, 4 grains.

Incompatibles: Acids, acid salts, alkalies and their carbonates, and vegetable astringents.

7. R.
Ferri phosphatis, ʒjss.
Quininæ phosphatis, gr. xlviij.
Strychninæ phosphatis, gr. jss.
Arseni trioxidi, gr. js. Misce.
Fiat massa in pilulas No. 48 dividenda.
Signa: Take one pill morning and evening.

R.
Potassii acetatis.
Potassii bicarbonatis.
Potassi citratis aa ʒii.
Aquæ q. s. ad ʒviij M.
Sig.: One tablespoonful, in water, three times a day.

8. *Carminatives* are remedies which are used to overcome flatulency and aid in the expulsion of gas. The chief *carminatives are:* Charcoal, peppermint, ginger, asafetida, camphor, ether, pepper, spirits, chloroform, and various aromatic oils. They may be administered by the mouth or as enemata.

9. METHODS OF INTRODUCING MEDICINES INTO THE SYSTEM:

(*a*) By the *skin*, or mucous membrane continuous with the skin, whether simply applied or rubbed in (liniments, ointments; painted on (pigments, etc.); worn on the skin (as a plaster or ointment); applied in a state of fine division by fumigation, with or without sweating; used as a gargle, injection, or wash; or insufflated on to a part. The effect desired is usually local only, but it may be general, many drugs being absorbed by the skin or exposed mucous membrane.

(*b*) By the *mouth*, to act locally on the alimentary canal, and to be absorbed from it, especially from the stomach.

(*c*) By the *rectum* (or *vagina* in the female), in the form of enema or injection (fluid), or of suppository (solid). Drugs may have to be given by the rectum instead of by the mouth, on account of some physical obstacle, repugnance on the part of the patient, or irritability of the stomach; or to spare the stomach in conditions of exhaustion. Again, the action desired may be a local one on the rectum and pelvic organs, *e.g.* to relieve pain, destroy worms or soften retained feces.

(*d*) By injection under the skin (*subcutaneous or hypodermic injection*); or into the tissues (*interstitial injection* and *infiltration*): excellent methods of admitting remedies into the system with certainty and despatch.

(*e*) By *application to wounds* or diseased surfaces, as lotions, dusting powders, gargles, injections, bougies, collyria; or by the *endermic* method, *i.e.* by being sprinkled on a blistered surface.

(*f*) By *inhalation*, the substances being volatile, and intended either to enter the blood through the pulmonary capillaries, *e.g.* chloroform, or to act directly on the parts to which they gain access in the form of smoke from medicated cigarettes, of insufflated powders, or of medicated watery vapours, sprays, or nebulæ.

(*g*) By *intravenous injection*, rarely practised in man. (Bruce's *Materia Medica and Therapeutics.*)

10. THYROID EXTRACT. "*Action*: It is a powerful vasomotor dilator, causing flushing of the cutaneous surface; large doses are apt to produce loss of appetite and diarrhea; it stimulates the cerebrum, and, given to excess, produces headache, restlessness, insomnia, palpitations, hot flushes, sweating, tremors, and even convulsions; it is excreted by the kidneys, and the quantity of urine is uniformly increased by it; it induces a greatly increased oxidation in the system.

"*Uses*: Myxedema; goiter (especially the hyperplastic follicular variety); sporadic cretinism; arteriosclerosis; delayed menstruation." (Wilcox's *Materia Medica.*) *The official term* is Thyroideum Siccum, or Dried Thyroids.

THERAPEUTICS

1. For *influenza:*

℞ Extracti aconiti .....gr. ijss
Quininæ sulphatis .....gr. xxiv
Pulveris ipecac et opii.....gr. xij
Acetphenetidini .....5j. Misce.

Fiant in capsulas No. xxiv.

Signa: Take two every three hours.

2. For *irritative cough:*

℞ Codeinæ sulphatis .....gr. vij
Ammonii chloridi 5jss
Syrupi tolutani 5ij
Aquæ quantum sufficiat ad 5iv. Misce.

Signa: One teaspoonful in water every two or three hours.

The codeine is a sedative; the ammonium chloride is an expectorant; the syrup disguises the taste of the ammonium chloride; and the water is a diluent.

3. See above, PHYSIOLOGY, 2.

4. In preparing a dietary, the first thing is to provide for a sufficient amount of protein; and then to add enough fat and carbohydrate to yield the requisite number of calories. Thus, for a man of average size and weight, and doing a moderate amount of manual work, the following may be suitable:

Protein, 120 grams.
Fat, 50 grams.
Carbohydrate, 500 grams.

This would yield the following amount of energy in calories:

Protein,	$120 \times 4.1 =$	492
Carbohydrate,	$500 \times 4.1 =$	2,050
Fat,	$50 \times 9.3 =$	465
Total,		3,007 calories.

5. The proportions given in the previous answer may be taken as normal. Deprivation of protein gives rise to inability to do muscular work, to imperfect tissue repair, to lowered vitality, and to a pale and puffy appearance.

6. *The main effect of venesection on the circulation* is a lowering of the blood pressure.

The favorable results of a venesection are manifested by the lowering of the blood pressure, slowing of respiration, quieting of the cardiac action, lowering of the body temperature, increase in the amount of urine excreted and of the solids in the urine.

7. The *succinate of sodium* is said to be of value in catarrhal jaundice, and also in delirium tremens.

8. PILOCARPUS. *Physiological action.*—It causes increase of saliva and of perspiration; increased peristalsis; it increases and then diminishes blood pressure and heart action; it causes the pupil to contract and depresses the nervous system. *Indications for use:* Bright's disease, uremia, eclampsia, pleural effusion, dropsy, and whenever prompt diaphoresis is required.

It has also been used in bronchitis.

9. *Hyoscine* "acts peripherally like atropine, and therefore will allay pain, will dilate the pupil, and will check secretion. But its action in the eye is more rapid and more powerful, a 1:500 solution dilating the pupil in ten to thirty minutes, and quickly thereafter paralyzing accommodation, while the effect passes fully away in three to five days. Centrally it differs from atropine in that the period of cerebral stimulation is short and is followed by prolonged mild depression of the psychic and motor centers—that is, the drug is narcotic. In excitable states, as in delirium or mania, it seems to have great power to lessen restlessness or excessive motor activity. Its use is not without danger, however, for it shows early depression of the respiratory and vasoconstrictor centers, and in a great number of instances has caused collapse. . . .

"Collapse is reported from the use of the drug in the eye.

"Its chief uses are: (1) As narcotic in the insomnia and excitement of acute mania, in delirium tremens, in the delirium of pneumonia (especially in alcoholics), and in the insomnia of alcoholism. (2) As a narcotic and peripheral sedative in treating the morphine and alcoholic habits. (3) As an anaphrodisiac. (4) As a mydriatic and cycloplegic—one drop of a 1:500 solution every fifteen minutes for four to six drops. (5) As a general anesthetic or as a preliminary to general anesthesia."—(Bastedo's *Materia Medica, etc.*).

10. *Senna* is a purgative, it stimulates the muscular coat of the intestine, acting chiefly on the colon. It is generally given with some other purgative. The chief preparations are the confection of senna, compound licorice powder, infusion of senna, and syrup of senna.

(*To be continued.*)

The Mutilated of the Great War.—According to compilations by the Red Cross the known mutilated total nearly 6,000,000. Of this number nearly one-half are furnished by France and Germany, the former leading the latter by a hundred thousand. Great Britain is third with well over a million, Italy fourth with over half a million, Poland fifth with 320,000, the United States sixth with nearly 250,000, while present day Czheko-Slovakia is seventh with 175,000. The Austria of today totals 164,000 and Jugo-Slavia has the same figure. Other figures are Canada with 88,000 (which, added to Great Britain, bring the grand total for that country up to a million and a quarter). The total for Roumania is 84,000 and that for Belgium 40,000. No figures are given for Russia or Bulgaria. These statistics, of course, give an imperfect idea of the total losses of the Teutons, as they are based wholly on postbellum geography. Apparently the countries which now represent ancient Austria furnish over half a million jointly, bringing the total of the Teuton armies to 2,000,000. The mutilated of Poland should be made up largely of former Russian soldiers.—*La Presse Médicale.*

Medical History.

NEW BOOKS AND OLD.

XIV. THE EDINBURGH SCHOOL OF SURGERY BEFORE LISTER.

By JOHN RUHRÄH, M.D.,

BALTIMORE, MD.

In the series of little Medical History Manuals published by A. and C. Black, London, there appeared in 1918 a volume written by Alexander Miles, Surgeon to the Royal Infirmary, Edinburgh, in which the author gives a very delightful account of the School of Surgery up to the time of their greatest master, Lord Lister. Lister marks an epoch not only in the history of the school at Edinburgh, but in the surgery of the world, so that future historians like Miles will probably write of "Surgery before" or "Surgery after Lister." In his preface Miles starts out with a paragraph on the value of the study of Medical History, which states so clearly its relation to a proper understanding of present day medicine that I cannot refrain from quoting it:

> The student of surgery who confines his reading to modern textbooks, which of necessity deal only with matters of present-day interest, fails to see the outlines of his subject in their true historical perspective. The existing state of surgery as a science and an art is duly presented to him, but the steps by which it has reached this state he has no means of tracing. The names of the old masters he may meet, but they remain to him but names attached to particular operations or instruments, and he gathers little of the part they played in the evolution of our knowledge and less of what manner of men they were. Seeing only the perfected results of the surgery of today, he fails, on the one hand, to realize the difficulties that had to be overcome by the pioneers of surgery, and, on the other, to grasp the real significance of the revolution effected by the master mind of Joseph Lister.

The School of Surgery goes back a long way, back to the year 1505 when the "Surregeanis and Barbouris" requested of the Town Council, shortly after they had been made a corporation, a request, "that we may have anis in the yeir ane condampnit man after he be deid, to make anatomea of, quairthrow we may heif experience, ilk ane to instruct utheris, and we sall do suffrage for the soule." Scotland in those days was in a pitiful plight. The people were ignorant and oppressed, and learning was not looked on with much favor. But these ruddy Scots of the Surgeon-Barber class gave evidence that they valued learning, for it was stipulated that no master of the craft should take an apprentice "without he can baith, wryte and reid", and realizing that sound surgery must ever rest upon a knowledge of anatomy, they represented in their petition, "that everie man that is to be maid frieman and maister amangis us be examit and previt in thir poyntes following—thatt is to say: That he knaw anatomea nature and complexioun of every member In manis bodie. And in lyke wayes he knaw all the vaynis of the samyn thatt he may mak flewbothomea in dew tyme. And als thatt he knaw in quilk member the signe hes domination for the tyme for every man aucht to knaw the nature and substance of every thing thatt he wirkis, or ellis he is negligent . . . ".

Thus we see that they were not quite like the old Scotch surgeon who was wont to say "Damn your anatomy, stick close to the bone." These canny Scots obtained other privileges than those of dissecting a condemned criminal once a year, and while they lost in the course of time, some of their franchises, one originally read, "That na person man nor woman within this burgh mak nor sell ony acquavitae within the same Except the saidis maisteris brether and frieman of the saidis craftes under the paine of escheit of the samyn but favouris."

The Barbers and the Surgeons remained leagued together up until 1722, when after many dissensions which led to litigation in the courts, the two bodies were separated by a decree of the Lords of Session. The Society of Barbers lingered on until 1892 when a father and son representing them, held the last meeting.

One of the most active of the early Surgeons was James Borthwick. He lies buried in Grey Friars church yard and his tombstone is the result of one of those curious fantasies illustrating the grim humor of the Scotch. Miles describes it as follows: "A dancing skeleton, holding at arm's length an open folio, is sculptured in the center astride the scythe of death; the plinth bears the familiar skull and crossbones, representations of coffins, spades, and picks; and the side panels are festooned round with various surgical instruments." This tombstone would make a fitting illustration to be included in F. Parkes Weber's book entitled "Aspects of Death Correlated and Aspects of Life," of which more at another time. Weber, however, has not seen fit to use it.

The first regular course of instruction in anatomy was made in 1694 by Alexander Menteith, who secured from the town council the bodies of persons who died in the Correction House and also the house for dissection. Unfortunately, for some reason, this course was discontinued after three years and Menteith turned his attention to teaching chemistry. In 1582 King James VI granted a charter of erection and for long after the institution was known as the College of King James. This college at Edinburgh paid no attention to the teaching of medicine until the first of the great Monros was made Professor of Anatomy in 1726. There had been some effort made to teach medicine before, the town council in 1685 having appointed three Professors of Medicine, but without salaries nor any assigned duties. The Physic Garden was established about 1668, and shortly afterwards a professor, on the fee of one guinea, undertook to demonstrate the plants and "to wait upon them at a solemn public herberizing in the feilds four severall times in every year." There were private lectures under the auspices of the Incorporation of Surgeons and these have been continued to the present time under what is known as the Extramural School. The beginning of the Medical School is due to the energy and ability of the first Monro. The Medical faculty lacked facilities for bedside instruction and in 1721 there was an attempt made to open a small hospital, but it was not until 1725 that Alexander Monro, with the aid of George Drummond, then the Lord Provost, was able to open a Royal Infirmary, which, as Miles truly says, "was destined to become one of the most famous Medical Institutes in the world."

One of the most remarkable of the practitioner surgeons of the time was Alexander Wood (1725-1807). He was better known at the time as "Lang Sandy Wood," and while he is more famed for his social qualities and his convivial habits than as a surgeon, his memory is still one of the cherished traditions of the Edinburgh School.

Oh, for an hour of him who knew no feud—
The octogenarian chief, the kind old Sandy Wood.

He was one of the chief members of the Gymnastic Club. In the poems of Andrew Duncan (1818) we find "a song composed on a memorable event in the annals of the Gymnastic Club."

Here lies Sandy Wood, a good honest fellow,
Very wise when sober, but wiser when mellow;
At sensible nonsense by no man excell'd,
With wit and good humour dull care he repell'd.
But though now he's laid low, we must not complain.
For, after a sleep, he'll be with us again.
Shed no tears, my good friends, wear no garments of sable;
Sandy Wood is not dead, but laid under the table.

A rhyming explanation of this "memorable event" was subsequently forthcoming which, while admitting that

'Tis true that once in evil hour
Beneath this table he did cour,
Which rais'd the tale, you may be sure,
That we had lost our Sandy,

went on to offer the excuse, always considered valid in these days, that

It was a glass that laid him low—
A glass his friend, and not his foe.

Those were merry days, and the accounts of such organizations as the "Sulphur Club," the "Hell Fire Club," and the "Demireps," make good reading, but I doubt that in this Sahara which we now inhabit anyone will ever have conferred on him, as did Sandy Wood, the diploma of Doctor of Mirth, which was given him by the Sons of Æsculapius in 1813. In spite of what the forward lookers of the present day will term his "indiscretions," Wood lived to the age of 82 and was until a few years of his death recognized as the leading surgeon in Edinburgh. Miles states that his grandnephew, Dr. Andrew Wood (1817-1884) introduced the practice of hypodermic medication and invented the hypodermic syringe.

The School of Surgery in Edinburgh dates from the second half of the eighteenth century. The founding of the Academy of Surgery in Paris and the enthusiasm of the French teachers, led Benjamin Bell and others to imitate their French colleagues. James Rae was the first to give a course in surgery apart from anatomy, and in 1776 the college approached the magistrates with a view to establishing a Professorship of Surgery within the University. This was violently opposed by Alexander Monro secundus, but after a bitter controversy in 1777 Monro was commissioned Professor of Medicine and particularly of Anatomy and Surgery. In 1804, the College of Surgeons having been unable to establish a separate Chair of Surgery in the University, appointed a lecturer with the title of Professor of Surgery in the Royal College of Surgeons. So it happened that a Surgical Professorship was founded in the Extramural School twenty-seven years before the teaching of surgery was separated from that of anatomy within the University. Two years later Thomson was appointed by the crown Professor of Military Surgery in the University and in 1831 he was made Professor of Surgery. The Extramural Chair was filled for the succeeding eight years by John Lizars, and when he resigned the Professorship was abolished owing to the fact that the Chair of Surgery had been definitely established in the University.

One of the most noted professors of surgery was Sir Charles Bell (1774-1842). He began his work on the nervous system in the Extramural School acting as assistant in the anatomical rooms of his brother John. Charles' ability as a draftsman led him to prepare the illustrations for the section on the nervous system of his brother's work on anatomy. When he was thirty years old he decided to move to London, where he made a great reputation. At the age of sixty-two, in 1836, he returned to Edinburgh as Professor of Surgery. At some future date I hope to review some of the contributions of Bell which are well worth the attention of modern students. Bell was followed in 1842 by James Miller (1812-1864) who held the chair up until the time of his death.

There were many curious things in connection with surgery in Edinburgh. Twenty-eight years before they were able to establish a definite Chair in the University there was a foundation made in 1803, by King George III, of a Chair of Clinical Surgery. Space prevents going into some interesting things in connection with this and also with the Chair of Military Surgery, established by the same monarch in 1806 and carrying with it an endowment of one hundred pounds a year or just twice as much as that given the Professor of Clinical Surgery.

Miles outlines the life and works of the various men who filled these chairs and also the more prominent teachers of the Extramural School, and he gives rather extended accounts, which it is a pity I cannot notice more fully, of Robert Liston (1794-1847) and of James Syme (1799-1870), the Napoleon of Surgery. Syme's name is associated with his method of amputation and so is reasonably sure of a permanent place in the history of surgery. He was a remarkable man, and when he passed there came Joseph Lister, as Miles says in closing:

In the radiant after-glow of Syme's fame the torch that Lister had lighted before he was called to fill the Chair of Clinical Surgery glimmered but feebly, yet ere long its lambent flame illumined the whole surgical firmament. That the light of Lister's genius shone at its brightest in her midst is the lasting pride of the Edinburgh School, but "many brave men lived before Agamemnon," and although we "are without a divine poet to chronicle their deeds," we would not willingly forget them.

Such in brief is the history of the Edinburgh School of Surgery up to the coming of Lister. With Lister dawned a new era, but the heritage from the earlier age should not be forgotten. Such works as these of Alexander Miles help to keep in mind the struggles and successes of the earlier surgeons.

Opotherapy in Heredosyphilis.—Fernet in the course of a long article on the treatment of syphilis mentions the pluriglandular treatment apparently indicated in certain types of the congenital form. One prescribes according to indication in part, but thyroid seems of value in most cases.—*Le Bulletin Médical.*

CLINICAL INDICATIONS OF THE ETIOLOGY OF DIABETES.*

BY J. W. MITCHELL, M.D.

MORRISTOWN, N. J.

THE question of the etiology of diabetes is important in relation to the theory of the subject and to practical prophylaxis, treatment and prognosis. The enormous increase of the disease, indicated by some statistics, amounting even to a multiplication of the incidence within the past few decades, is explained by Joslin[1] as representing chiefly improved diagnosis, though there is a possibility of some degree of actual increase connected with advanced civilization (nervous stress, sedentary life, elevation of the average nutritive level, obesity) or to possible unknown factors.

As a clinical contribution to this subject, the records of 229 diabetic patients observed by the writer in the Physiatric Institute, under the direction of Dr. Frederick M. Allen, between July 15, 1919, and January 1, 1921, have been analyzed with a view to suspected etiologic agencies. The viewpoint has been chiefly that afforded by the newer conceptions of diabetic pathology,[2] but the older hypotheses have also received consideration. A well-rounded study must rest on cases which are adequately investigated from all angles. For example, the factor of heredity is important, and the convincingness of the evidence concerning any suspected etiologic agency in any individual diabetic is different if this patient is free from any discoverable hereditary taint, or if on the other hand he is strongly predisposed by heredity. The family history is also the part of the record which is subject to the most serious deficiencies and inaccuracies, since very few persons actually have accurate knowledge of the causes of death or illness of their immediate relatives. Chiefly on this account 113 cases were rejected, and the study was based upon 116 diabetics who could give reasonably trustworthy statements concerning diseases in their grandparents (exceptionally the great-grandparents), parents, uncles and aunts, cousins, nephews and nieces, and children. Also, in all instances the inquiries into possible acquired causes, particularly constitutional or local infections which might stand in etiologic relationship to the diabetes, were pursued more carefully than is customary in average history taking. The suggestive causative agencies may be divided into hereditary and acquired.

I. *Hereditary Causes.*—The possible hereditary causes may be divided into those pertaining to the race and those pertaining to the immediate family.

A. Race: Of this series of 116 patients, 65 patients or 56 per cent were Jewish. In the interpretation of these figures due regard must be paid to the large Hebrew population of New York, but still the vast majority of the population from whom patients are drawn are non-Jewish. The proportion of Jews may be swelled somewhat by their knowledge of diabetes and its symptoms and by their disposition to seek medical care. A more important disturbing influence may be found in factors such as mode of life, nervous qualities, deficient exercise, over-eating, obesity, etc., which are common racial characters but not strictly hereditary. Without attempting to go more deeply into the cause, this record may at least be said to support the prevailing belief in a specially high incidence of diabetes among the Jewish race, and race must therefore receive consideration among the possible predisposing causes in any instance.

B. Family: The observations covered the incidence of certain associated disorders, obesity, and diabetes.

TABLE I.—ASSOCIATIONS OF METABOLIC DISORDERS IN INDIVIDUALS AND FAMILIES.

	A. Diseases in Blood Relatives of 116 Diabetic Patients.		B. Complicating Disorders in 116 Diabetic Patients.		C. Diseases in Blood Relatives of 112 Non-Diabetic Patients.	
	Absent in 40 Cases	Present in 76 Cases, as Follows:	Absent in 79 Cases.	Present in 37 Cases, as Follows:	Absent in 29 Cases.	Present in 83 Cases, as Follows
Arteriosclerosis, hypertension or apoplexy		22		26		48
Nephritis		31		8		38
Diabetes		78				43
Obesity		111				20
Cancer		21		1		34
Tuberculosis		32		5		33
Cardiac disease		28		4		21
Thyroid disorders		4		3		5
Nervous or mental diseases		8		3		9
Cirrhosis of liver		0		0		2
Bronchial asthma		5		0		3
Rheumatoid arthritis		4		0		2
Gout		1		0		0
Constitutional inferiority		1		3		0
Pernicious anemia		1		0		1
Progressive muscular atrophy		0		0		1

1. *Associated Disorders.*—It has been the opinion of J. R. Williams[3] and many of the classical writers that nephritis, arteriosclerosis, and other metabolic disorders are significantly prevalent in the same families with diabetes. Diabetes has also been viewed as a degenerative disorder, associated in the same individuals or families with nervous ailments and stigmata of degeneracy. Infections such as

*From the Physiatric Institute, Morristown, N. J.

syphilis (mentioned separately below) and tuberculosis have sometimes been regarded in the same connection not as causes of diabetes but as indications of constitutional taint. Cancer is sometimes considered in a similar sense. Table I has therefore been arranged to show, in its division A, the occurrence of these other diseases in the families of these 116 diabetics. As an additional feature, division B shows the occurrence of these disorders in the same individuals with diabetes. For comparison, division C embodies a similar study of the family history of 112 non-diabetics, the great majority of whom were nephritic and hypertension patients under treatment in the Institute, while a minority were persons examined on account of suspicion of metabolic disease.

Certain crudities are unavoidable in any such tabulation. Arteriosclerosis and hypertension are by no means synonymous, but were best lumped together with apoplexy for this presentation. They are not sharply distinguishable from nephritis or cardiac disease, but the chief abnormality was chosen for classification as well as possible. Cardiac disease as a complication of diabetes could not be taken to mean the slightest detectable abnormalities, but could include only serious cases on a par with those mentioned in the family histories. The question of primary and secondary etiology required consideration. In only one instance was there any strong suspicion that arteriosclerosis may have caused the diabetes. In at least one instance tuberculosis apparently antedated the diabetes. In general, also, the diabetes cannot be regarded as the primary cause of the other disorders, though patients with active diabetes are notoriously susceptible to infections and injuries in all parts of the body. For one example, they have been considered specially susceptible to arteriosclerosis, and occasionally a high blood pressure may be found to fall by simple treatment of the diabetes. Another interpretation is that the original toxic or infectious cause of the diabetes injured other organs besides the pancreas, so that the diabetes becomes complicated with the symptoms of these other injuries. The special status of obesity is discussed below.

Considering division B first, it may be deemed certain that the proportion of 37 complicating disorders in 116 individuals is higher than would be found among the population at large at corresponding ages. This ratio is increased by the fact that the same patient occasionally had several distinct complications, so that division B actually contains 51 examples of the disorders in question. With a certain small allowance for the predisposing influence of the diabetes, there is still ground for the above-mentioned conclusion that a considerable proportion of diabetics have suffered injuries in other organs than the pancreas.

With regard to division A, it must be recognized that complete family histories of any group of persons must show a high proportion of certain chronic diseases, for the very reason that these diseases are so widely prevalent. Though the proportion is high for the diabetics in division A, it is even higher for the non-diabetics in division C. The figures shown in the column headings of these two divisions represent the number of patients having a history of constitutional disease among their blood relatives, and these are necessarily increased greatly by the multiple instances occurring in the respective families, as shown in the detailed figures of the columns. Real completeness would have required a study of the family history of a similar number of persons free from metabolic disease. It is evident, however, that nephritis, arteriosclerosis, and hypertension (in the sense of the severe fatal forms here referred to) hold an abnormally high position in relation to cancer and tuberculosis here in comparison with vital statistics for the population at large. It may therefore be inferred that these disorders tend to be associated in the same families. The hereditary tendency is strongest for the identical disorder. The actual examples of nephritis, arteriosclerosis and hypertension are more numerous in division C than in division A, but this demonstration could be made much more striking through proper allowance for the fact that a considerable proportion of the diabetics with cardiovascular-renal disorders among their relatives also had these troubles themselves, and the highest proportion of negative family histories in division C were found among the persons of this group who had little or no metabolic disease. Therefore, notwithstanding the interrelations, the fact remains that diabetes is by far the leading disorder in diabetic families, and nephritis similarly in nephritic families. No similar association of diabetes with thyroid, nervous, or mental troubles, cancer, or constitutional inferiority is indicated in these family histories.

2. *Obesity.*—Strictly accurate statistics on familial obesity are unobtainable, partly because no precise line can be drawn between obesity and its absence, and partly because it is generally impossible to learn the exact number of relatives who have been obese. The figures shown in division A of Table I are conservative, being based upon a definite history of marked obesity in relatives of whom the patients had sufficient information, and it may thus be assumed that a considerable number of obese individuals escaped notice. In most instances the examples of obesity in a given family were multiple. The list thus includes 111 obese relatives of the 116 diabetic patients, as opposed to only 20 obese relatives of the 112 non-diabetic persons (division C). As the statistical method was the same in the two series and involved equal chances of error, the result confirms the prevalent view that obesity is specially associated with diabetes in families. The question must be left open to what extent this association depends upon endocrine or other inborn peculiarities, and to what extent it represents merely family habits of gluttony giving rise to both obesity and diabetes. It may be mentioned that obesity has been noticeably prominent in Jewish families in combination with excessive eating.

3. *Diabetes.*—A definite history of diabetes in some member of the immediate family was obtained in 54 of the 116 diabetic cases (46.6 per cent). Owing to the multiple instances of diabetes in some families, the total number of diabetic relatives of the 116 diabetic patients was 78, as shown in division A of Table I. This number is disproportionately large in comparison with the 23 diabetic rela-

tives of the 112 non-diabetic individuals (division C). It must be repeated that even this figure 23 is artificially swelled by the fact that so many of the non-diabetic individuals came for examination because they had diabetic relatives under treatment in this Institute. In addition, reference may be made to observations reported by Sherrill[4] indicating that the number of examples of diabetes in diabetic families may be greatly enlarged by the many latent or potential cases revealed by blood sugar analyses and glucose tolerance tests.

Heredity is frequently not the sole etiologic possibility in the cases classed as hereditary. Acquired factors often enter in as confusing elements. One of the commonest combinations may be summarized in "race, heredity, obesity, over-eating." Infection also requires consideration. Following in general the classification used in Chapter VIII of the Rockefeller Institute Monograph No. 11, the cases in this series may be analyzed as follows:

(*a*) Cases without known heredity.—These comprised 62 cases, or 53.4 per cent, in the present series. Deficiencies in such a record must be ascribed to lack of complete information by the patients, inadequate or incorrect diagnoses by physicians in the past, and the possible number of latent cases which can be discovered only by the most recent methods. In general, it appears that the non-hereditary class will diminish as investigation becomes more accurate, and an hereditary element may be suspected in the majority of diabetic cases.

(*b*) Cases of marked hereditary character, or without other known etiologic factors.—The occurrence of 54 familial cases, or 46.6 per cent in this series, was mentioned above. It is easy to find examples of seemingly pure hereditary type, where the number of cases in a family is large and diabetes appears, sometimes in infancy, without the slightest suggestion of any cause other than heredity. The great majority of cases occur at a later age and under more mixed conditions. A new turn is given to this problem by the pathological studies of Allen, indicating that even in the seemingly pure hereditary cases evidences of pancreatitis are commonly distinguishable at autopsy. As the present observations are entirely clinical, and so many details of clinical histories are confusing and open to different etiologic interpretations according to the viewpoint of the investigator, no attempt is here made to subdivide the hereditary group accurately between pure and mixed cases.

(*c*) Familial diabetes due to transmitted infection.—The possibility is open, chiefly with regard to syphilis, that infection transmitted through several members of a family may attack the pancreas and thus cause diabetes in some or all of them, without any true hereditary factor being involved. Opinions have differed widely concerning the frequency of such an etiology, but the general decision is that it is comparatively rare. The majority of cases in the present series were not subjected to the Wassermann test, but this test was performed in all instances when the slightest suspicion was created by either the history or the physical examination, and when indicated was performed upon both the suspected parent and the child. In no instance was familial diabetes thus traceable to syphilitic infection, and this series thus agrees with the general experience that such causation of diabetes is uncommon.

(*a*) Cases due to accidental acquired infections.—The following examples are chosen from this series to illustrate confusing combinations of heredity and infection:

Patient No. 132 was a girl of 22 years, who gave a history of diabetes in her paternal grandfather and four of her uncles and cousins. Her own record was negative except for mild childhood diseases and malaria at 18. At the age of 19 she experienced a severe attack of epigastric pain, with icterus. The condition was carefully studied in a New York hospital and a diagnosis of cholecystitis was made. During this time glycosuria was found for the first time. The diabetes proved to be easily controllable by diet, but in the course of the next 3 years there were several wide variations of the tolerance, not connected with alterations of diet but accompanied by slight abdominal pains and a doubtful icteroid tint of the skin.

Patient no. 44 was a seemingly normal Jewish boy aged 5 years. Both grandfathers and the paternal grandmother were obese and diabetic. In May, 1918, the child sustained a rather deep cut of the face, which became infected and drained for about a month. Six months later enuresis began, and a test of the urine revealed sugar.

Patient No. 166 was a small, poorly developed Jewish boy of 2½ years. The father was living and diabetic, and the paternal grandmother and maternal grandfather died of diabetes. In August, 1919, the child had measles and during convalescence was allowed more candy than usual. About Oct. 1, 1919, diabetic symptoms were first noticed by the parents and glycosuria found by a physician.

Patient No. 184 was an apparently normal Jewish girl of 14 years, with a history of diabetes in her father and two maternal aunts, all three of whom were living. Her only known illnesses were measles and mumps in early childhood and a severe "catarrhal" icterus in 1916. The first diabetic symptoms noticeable to the parents appeared in January, 1919.

II. *Acquired Causes.*—Sex and age are traditionally discussed as factors influencing the incidence of diabetes. Joslin states that diabetes is more frequently treated in males but that more females die of the disease. The present series of 116 cases included 70 males and 46 females. The increasing frequency of diabetes with advancing years is also commonly recognized. The present series comprised 4 cases in the first decade, 14 in the second decade, 18 in the third decade, 23 in the fourth decade, 27 in the fifth decade, 26 in the sixth decade, 2 in the seventh decade and 2 in the eight decade. Such figures are mostly explainable on a simple rational basis. Formerly, at least, women had their urine examined less often than men, hence diagnoses were apt to be fewer and later. In children and young persons, there has been less time for heredity to manifest itself, and advancing years bring an increasing series of actual etiologic factors such as infections, gluttony and obesity. The incidence of diabetes thus rises up to the later decades (in this instance the sixth), until the absolute figure falls corresponding to the fewer persons alive at very advanced ages. It is unnecessary to

consider age and sex in themselves as etiologic factors.

The three agencies which merit principal consideration as possible acquired causes of diabetes are (A) nervous disturbances, (B) over-eating and obesity, (C) infections.

A. Nervous Disturbances:—These receive attention because of the high importance attributed to them by classical writers, notably Naunyn, and the persistence of a widespread belief in the nervous causation of diabetes. There was no example of traumatic diabetes in the present series. A suspicion of this sort was possible only in the case of a patient who had been struck on the head with a small stone two years before the onset of diabetic symptoms, but the injury seemed too slight to be significant. Several patients suggested that their diabetes had been brought on by worry, but this notion was chiefly derived from the current theories which they had heard discussed, and it was not possible to compile any statistics distinguishing between patients who had had special worry and grief and those who had not. Allen has discussed the nervous hypothesis of diabetes, and has stripped it of most of its importance by two principal arguments: first, the world war with all its physical and metal shocks and stress did not increase the incidence of diabetes;[3] second, the pathology of diabetes disagrees with the assumption of a merely nervous etiology. The possibility remains open that the nervous system may play some minor part as an exciting or aggravating factor in diabetes, but with more careful study it tends to retreat more into the background.

B. Over-eating and Obesity:—Sixty-nine patients (approximately 60 per cent.) of this series were obese when received or gave a history of obesity. The proportion might have been increased by considering all excesses of weight above the average set by insurance companies, but the above figures refer to marked and unquestionable obesity. Other patients who were not notably obese gave a history of gross excesses of diet, sometimes particularly in sugar and starch and sometimes in food in general. These records were not classified, because it is difficult to draw an exact line between excessive and normal eating. Continued excesses naturally lead to obesity, and there was no other apparent cause for the excess weight in the patients who were obese, and no difficulty in reducing their weight by limitation of diet. A further discussion of this factor might have been undertaken, had not Joslin[4] recently covered this subject thoroughly and convincingly. Also, as it has been shown experimentally that an existing diabetes can be aggravated or controlled by increase or reduction of the body weight, it is safe to assume that the same influence may determine whether a diabetic tendency becomes active or remains latent. There is no evidence that either gluttony (in carbohydrate or other food) or obesity can be a primary cause of diabetes in an otherwise normal individual. Fibro-fatty changes, when present in the pancreas, must be attributed to another origin, and excessive diet and obesity must be regarded only as a secondary or exciting cause.

(C) Infections:—There is a considerable literature of reports of diabetes coming on acutely during or following acute infection. Saundby[5] reported two such cases in 1890. In a clinical lecture in 1896, James[6] stated that there had been a distinct increase in the number of cases of diabetes admitted to the hospital following epidemics of influenza. This suspicion concerning influenza was renewed by Hirschfeldt[7] in 1908 and particularly of Motzfeldt.[8] Joslin states, "In only a few instances have I been able to associate infectious disease with diabetes; in fact, in only 28 cases of my series"; also, "On the other hand, the marked lowering of tolerance for carbohydrate in diabetic patients when an infection appears is an emphatic demonstration that this subject should be thoroughly investigated."

From purely clinical evidence, it is seldom if ever possible to decide whether any case of diabetes following infection is primarily caused by the infection or has previously been latent and is merely excited into activity by the infection. Other factors, such as heredity, often serve further to confuse the question, as previously mentioned. Allen[2] has clarified the subject by showing, from the literature and by personal observations, (*a*) that pancreatic disease is very common, and in addition to true chronic pancreatitis, various acute infections are accompanied by acute inflammations and necroses in the pancreas which may give no perceptible clinical symptoms at the time but nevertheless leave the organ permanently damaged and scarred thereafter; (*b*) that all accurately studied cases of diabetes show pancreatic lesions of this character at autopsy, and even when the existing fibrosis or other pathology is slight (so that the pancreas has sometimes been reported as "practically normal"), these changes are nevertheless important as remains of a former acute inflammation which has damaged the islands of Langerhans in structure or function; (*c*) that these conditions can be imitated by experimental aseptic inflammation of the pancreas in experimental animals, which produce both diabetes and the various degrees of scarring in the pancreas. With the support of this pathological and experimental evidence, it is no longer necessary to require strict clinical proof that a given infection gave rise to diabetes; but just as heart disease is connected with tonsillitis or some other antecedent infection or in other cases some portal of infection is assumed if not known, so also in taking the clinical history of a diabetic patient particular care should be employed to inquire for infections which may have been responsible for setting up pancreatitis. In the majority of cases no positive clinical relationship of this character can be traced, and the origin of the pancreatitis (the occurrence of which must still be assumed on the basis of autopsy evidence) must remain unknown. In a large minority of cases, careful questioning will reveal relationships which add support to the infectious theory of the etiology.

Among the 116 cases of the present series, 51 were found with histories sufficiently suggestive to warrant tabulation.

Table 2 shows 8 cases in which diabetic symptoms followed immediately upon local or general infection. The first 4 are cases of gallbladder infection, presumably communicated through the ducts or lymphatics to the pancreas. These cases all belong in this category, even when the actual diagnosis of diabetes was delayed for 6 or 9 years, because there was

a clear history of typical diabetic symptoms dating back to the time of the cholecystitis. The last four cases are general infections, 1 of streptococcus, the other 3 of influenza, thus adding to the bad repute of the influenza bacillus in connection with diabetes. The close relationship in these 8 cases leaves scarcely any doubt of the significance.

TABLE 2.—EIGHT CASES IN WHICH INFECTION WAS AN IMMEDIATE ANTECEDENT OF DIABETES.

Serial No.	Nature of Infection.	Predisposing Factors.	Time Elapsed.
111	Acute pancreatitis, diagnosed clinically, accompanied by icterus.	Overeating and obesity.	Never convalesced. Diabetes diagnosed in six weeks.
132	Acute epigastric disturbance with icterus, probably cholecystitis.	Heredity.	Glycosuria found during attack.
83	Chronic cholelithiasis, frequent attacks, chronic icterus.	Race.	Diabetes diagnosed after six years.
36	Puerperal sepsis at 25 and 40 years. Chronic cholecystitis for 15 years. Arthritis deformans for 18 years.	Race, obesity.	Diabetes diagnosed 9 years after onset of cholecystitis.
78	Acute streptococcic adenitis, simulating lymphatic leukemia.	Heredity.	Glycosuria found during attack.
124	Influenza.	Lead poisoning abdominal type.	Glycosuria found during convalescence.
218	Influenza.	Heredity, menopause, sedentary life, obesity.	Glycosuria found during convalescence.
204	Influenza.	Race, heredity, overeating, obesity.	Glycosuria found during convalescence.

Table 3 presents 43 cases in which the relationship is less immediate and clear, but in which the general knowledge of the subject now permits tracing a suggestive sequence of cause and effect. First are placed 10 cases of liver or gallbladder disease. Next come 9 cases of chronic gastrointestinal complaints, which are characteristic of a certain type of diabetics and are presumably connected with pancreatitis even in the absence of steatorrhea or other signs of extreme degree. The rest of the table is made up of a mixture of general and localized infections which may be suspected as responsible for the diabetes through pancreatitis.

The outstanding cause of a true chronic pancreatitis is syphilis, here represented by 3 cases. Single or successive acute infections constitute the remainder of the list. Two points in connection with this table call for special discussion.

First is the time elapsed before the apparent onset of diabetes. When such onset occurs within a few months, the causal relation of the primary infection may be considered clearest. Other cases have been listed in this table of suggestive relationships, even when the diagnosis of diabetes has been made 5, 10 or even 20 years after the original infection. In some of these instances it has been evident from the patient's history that active diabetes has been present for many years and only the diagnosis has been lacking. A further link in this evidence is furnished by the very recent observations of Sherrill,[4] who has shown that a "prediabetic" or latent diabetic state may exist for years with or without occasional glycosuria or other symptoms, yet with a deficiency of carbohydrate assimilation plainly demonstrable by glucose tolerance tests and serving as a clear warning of the coming

TABLE 3.—43 CASES SHOWING A SUGGESTIVE RELATIONSHIP BETWEEN PATHOLOGY OR INFECTION AND DIABETES.

Serial No.	Pathologic Condition.	Additional Causative Factors	Time Elapsed.
31	Hepatic enlargement, typhoid at 18	None known.	Six months after hepatic enlargement
126	Hepatic enlargement.	Heredity, overeating, carbohydrate excess.	Indeterminate.
149	Hepatic enlargement.	Race, overeating, obesity.	Indeterminate.
219	Hepatic enlargement.	Pregnancy	Indeterminate.
223	Severe catarrhal icterus.	Heredity, overeating, obesity.	20 years.
200	Enlarged spleen at 26. Severe icterus at 42	Race	6 years.
168	Acute catarrhal icterus in 1916, hepatic enlargement at admission.	Race, overeating, carbohydrate excess, obesity	Within a year.
191	Acute catarrhal icterus.	Heredity, carbohydrate excess.	Within a year
60	Acute hepatitis with icterus between 14 and 18. Acute icterus at 26, paratyphoid fever at 28.	Heredity, overeating	1 year after paratyphoid.
26	Dysentery, melena and chills followed by cholecystitis.	Heredity, overeating, obesity.	Indeterminate.
125	Chronic dyspepsia	Carbohydrate excess.	Indeterminate
24	"Stomach trouble" 16-24 years.	Moderate obesity.	Indeterminate.
214	Chronic indigestion.	Heredity, overeating	Indeterminate.
90	Severe gastrointestinal disturbance as child.	Heredity, overeating, obesity.	Indeterminate.
51	Gastrointestinal disturbances.	Heredity, obesity.	Indeterminate.
130	Chronic indigestion.	Race Constitutional inferiority.	Indeterminate.
159	Chronic indigestion.	Race. Overeating, obesity.	Indeterminate.
220	Chronic indigestion	Race. Heredity.	Indeterminate.
217	Chronic indigestion	Race. Overeating, carbohydrate excess, obesity.	5 years
231	Syphilis, acquired, treated with mercury and potassium iodide.	Race, heredity.	20 years
47	Syphilis, acquired, treated with salvarsan and mercury.	Race, heredity.	15 years.
141	Syphilis, acquired, no treatment.	Race, heredity, Overeating, obesity.	Indeterminate.
54	Acute appendicitis at 13 and 21. Bilateral oophorectomy at 23.	Artificial menopause.	Indeterminate.
76	Furunculosis for years, frequent respiratory infections.	Heredity, constitutional inferiority, carbohydrate excess	Indeterminate.
192	Mumps, measles, chickenpox, influenzal pneumonia, chronic pan-sinusitis	Race	Indeterminate.
156	Chickenpox, measles, mumps, typhoid fever.	Poor development, carbohydrate excess.	Indeterminate.-
43	Severe sinusitis, 1914, chronic since.	Race	4 years.
195	Acute and chronic nephritis.	Race Carbohydrate excess.	7 years after diagnosis of nephritis.
140	Phlebitis following childbirth, specific salpingitis	Race. Heredity.	10 years.
146	Fistula in ano from 15 to 27, badly infected much of that time.	None.	12 years.
150	Two rectal abscesses in past three years, frequent tonsilitis	Race, carbohydrate excess.	2½ years
137	Acute appendicitis at 51, chronic intestinal obstruction past 4 years.	Heredity, overeating.	Diabetes discovered by blood analysis.
1	Acute suppurative appendicitis, frequent tonsilitis, two attacks of measles.	None.	6 months.

TABLE 3.—Continued

Serial No.	Pathologic Condition.	Additional Causitive Factors.	Time Elapsed.
41	Scarlatina, pneumonia, measles as child, endocarditis at 18, gangrenous appendicitis at 25, chronic nephritis for three years prior to onset of diabetes.	Poor development, overeating.	6 months after appendicitis.
187	Measles, scarlatina, diphtheria, and pertussis between six and eight years.	Overeating, carbohydrate excess, obesity 8 to 11 years.	3 years.
184	Measles, mumps and severe catarrhal icterus 3 years prior to onset.	Race, double heredity	3 years.
205	Mumps, measles, chickenpox, frequent tonsilitis.	Heredity, badly balanced diet.	Indeterminate.
97	Measles, preceded by mumps and chickenpox.	Heredity, carbohydrate excess	2 months.
166	Measles.	Race, double heredity, carbohydrate excess.	2 months.
44	Measles, infected wound of face.	Race, double heredity.	6 months.
196	Mumps, measles, scarlatina, typhoid, diphtheria.	Race, heredity, overeating, carbohydrate excess.	6 years.
70	Severe typhoid fever, three relapses.	Overeating, carbohydrate excess.	6 years.
85	Frequent severe otitis media influenza in 1914	None.	8 to 9 months

of outright diabetes in the future. Under these circumstances the cause which damages the pancreas must often be sought at a period years before the diagnosis of diabetes, and a fallacy must lie not in attempting to trace the clinical history in such a sequence but rather in trying to assume some immediately associated factor or symptom (such as a nervous state) as the cause of a diabetes which has actually been coming on for many years.

Second is the confusion introduced by other factors which enter into the history of many or most cases. One of these is heredity. Allen's studies have brought into prominence the fact that the pancreatic pathology is entirely similar in hereditary and non-hereditary cases; in other words the pathology indicates pancreatitis as the cause of the diabetes even in hereditary cases. "If this be true, the problem of hereditary diabetes becomes simply the question why certain families or races are specially subject to pancreatitis or to a particular form or consequence of it." "With diabetic heredity such inflammations may be either more frequent, or, by reason of an inherently subnormal functional power of the organ, more serious in their consequences; and accordingly there will be special interest in examinations of the pancreas of both the non-diabetic and diabetic members of diabetic families." Over-eating and obesity, as elsewhere mentioned, cannot be regarded as primary causes of diabetes, but undoubtedly contribute to convert any latent tendency into the active disorder. None of these factors, therefore, detract from the value of attempts to trace the origin of any case of diabetes to its primary infectious cause.

Summary and Conclusion.—The recent advances in the knowledge of diabetes have given a fairly clear explanation of the etiology. Pancreatitis is very common, often giving no recognizable symptoms even in acute cases, but it leaves the pancreas more or less damaged in structure and function. In the majority of cases the injury is relatively slight and the margin of safety of the organ enables it to continue its functions. In very numerous cases, however, the islands of Langerhans are injured to an extent which produces various degrees of diabetic tendency. With sufficiently severe injury the outbreak of diabetes may be immediate; with the milder grades it may be postponed for years.

Some races and families are for unknown reasons specially subject to infectious or toxic damage of certain viscera; the lesions are readily revealed by autopsies, and clinical histories show the high frequency of the hereditary association. When an individual, with or without hereditary susceptibility, becomes potentially diabetic through pancreatic injury, over-eating (perhaps of carbohydrate especially) and obesity contribute to increase this tendency and develop an active diabetes, while abstemious living may keep the disorder latent throughout life. Because the degree of pancreatic damage which suffices for active diabetes in an obese person is insufficient for producing it in a thin person, diabetes developing in thin persons is generally more severe than that which occurs in the obese.

Prevention of diabetes, even in the susceptible families, may be expected more and more from prevention of the primary cause, through prevention and improved treatment of infections. Avoidance of gluttony (in carbohydrate or other food) and of obesity may be expected to prevent a large proportion of latent cases from developing. Precautions against infections (early removal of threatening foci in teeth, tonsils, appendix, galbladder, etc.) and against dietary excesses are most important in the members of predisposed families. The very few causes mentioned are probably all that require serious attention, and prophylaxis against the primary infectious and secondary dietary agencies may be hoped gradually to reduce the heretofore rising incidence of diabetes.

Action of the Rabbit Spirochete on Man.—Recently the rabbit has been found to suffer from a spirochetosis natural to itself, a fact which doubtless throws some light on the susceptibility of the animal to syphilis. The lesions, which are papulo-crustaceous, attack the genitals and nostrils. This spirochetosis has been encountered in the rabbits of numerous European countries and has received the name of *S. cuniculi*. Levaditi and others have been testing this spirochete in mankind, but thus far the latter has proved immune to it.—*Gazette des Hôpitaux.*

CANCER A MUTINY OF BODY CELLS.

By L. DUNCAN BULKLEY, A.M., M.D.,

NEW YORK

SENIOR PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL; MEMBER OF THE AMERICAN ASSOCIATION FOR CANCER RESEARCH

SOME one has likened the systemic process of carcinosis, which results in the local lesions in various locations of the body to which have been given the name of cancer, to a mutiny or rebellion of certain previously normal or healthy body cells to the conditions under which they exist, in regard to nourishment, hygienic surroundings, personal treatment, etc. While the suggestion was briefly considered in my recent book, the subject is such a wide and important one, and opens so fully all the relations of cancer, that it will bear further development.

We can understand how the body cells rebel against wrong conditions of nourishment, in the light of the remarkable book by Quevli,[1] in which the subject of "Cell Intelligence" has been worked out and developed scientifically, and so convincingly that there is no question but that their aberrant and riotous action is the result of the condition in which they find themselves.

A regiment of soldiers has been sent far away, as, for instance, to Siberia, and owing to difficulties of transportation and lax and bad management, mainly on the part of subordinates, the food and other elements of life have become wrong and in every respect intolerable. Finally a single soldier or two, representing individual body cells, rebel, and declare to their comrades that they will not stand it longer, and presently fifty or more agree with them, and they propose to kill their officers and return home. The colonel of the regiment hears rumors of the dissatisfaction and investigates, and happens in at a meeting of the plotters, and quickly surrounds and arrests them and has them all shot, just as the surgeon removes the riotous group of cells forming the tumor called cancer.

But if the intolerable conditions of life remain the same, this may not prevent another group of riotous soldiers, or cells, forming in the same locality or elsewhere in the regiment or body, and the surgical removal or shooting of these will not prevent still other mutinous bodies forming, until the whole regiment or body becomes affected, and subsequent drastic treatment ends the life of the regiment or body. This we see every day in cancer, for all recognize and know that repeated surgical operations end disastrously, and Ewing[2], as a result of pathological observation states, in regard to mammary cancer, "There can be no doubt that operation shortens life and aggravates the terminal suffering in a great majority of recurrent cases."

What now happens if a good and compassionate colonel is in charge of the same regiment? Hearing the rumors of dissatisfaction he investigates and happens in at the same meeting, or listens outside, in which the soldiers, or cells, are complaining to one another and proposing to kill their officers, as the cancer cells, if the bad conditions of body remained unchanged would of themselves kill the patient. The good colonel hears the soldiers declaim to each other the various sources of discontent which were leading them to riotous and mutinous conduct. "The beef and canned goods are rotten," "The potatoes are frosted and decayed," "The canned milk is all sour," "The cereals are full of maggots," "The black bread is sour and mouldy," "The drink called coffee is made from acorns," etc., etc. Moreover, "The hygienic conditions are dreadful," "The wooden flooring of the tents is decayed, and some are sleeping on the ground," "The tents are worn out and leak in the rain," "Filth prevails everywhere," "There is an insufficient supply of blankets, and the tents not being warmed and the clothing poor and worn out, some perish from the cold, while all suffer," "The shoes are worn out, and those that were provided did not fit, but caused sore feet," "There were no gloves or mufflers to protect against the bitter cold," etc., etc. "Let us kill our officers and go home."

The good colonel hears all this from the outside and steps into the gathering and says, "Boys, I have been hearing all that you have said; why did you not come right to me? The things you mention are shameful and should not be, and I have been derelict and should have looked into and rectified them before; but all shall be changed and you shall all be the good soldiers, such as you always were before we came to Siberia."

By some means or other, with great care and attention to every detail he secures better transportation and supplies them with the proper and best food imaginable and rectifies all the hygienic and personal elements which were wrong. He dismisses all the commissary agents and also the noncommissioned officers, appointing new ones who carry out scrupulously all his personal orders, and he places everything as it would be in an ideally regulated camp, under his own personal supervision, in every detail.

What now happens to this discontented, riotous, and mutinous group of soldiers? There is no need of shooting them because they have threatened to kill their officers and go home, for they thought they had, and did have, just reason for complaint. Now all is changed, and they take up their former life of obedience to just commands, do their work and drilling cheerfully, and become again even better soldiers than before, because they have experienced the beneficial results of human intelligence and compassion, instead of the irritating and harmful influence of ignorance and brute force.

The simile applies perfectly to cancer, as I have repeatedly shown elsewhere, and as many will testify, who have, with great patience and perseverance, applied the right principles of correct dietary, hygienic, and medicinal treatment in carcinosis, wherever its local lesions are manifested in various parts of the body. Of course we have not reached the point where every case of cancer, in every stage of the disease can be cured, but under sufficient and exactly proper medical management there need not be the 90 per cent. of ultimate deaths from cancer that surgeons acknowledge to be the case at present; early cases that have not been operated on yield in a large proportion, as

has been repeatedly shown, while even advanced, inoperable, and postoperative cases show plainly the beneficial results of procedure along these lines, with some recoveries. Moreover, when the lesions and the real carcinosis disappear, with the removal of the causes, the cure is complete and permanent, until new causes arise, even as in the army there would be no more mutiny when the reasons for it had ceased to be operative.

The simile of a mutiny also explains the occurrence of metastases. We can understand how one or more members of the first disaffected group of soldiers might go to another company and call attention to the same grievances which had caused them to rebel, and thus a metastasis or new group would arise elsewhere and spread to any dimensions. And so again from this second disaffected group some might go elsewhere, until the whole regiment was infected. With the intelligent body cells of cancer the same can take place, if the constitutional conditions remain active.

Finally, the simile of a mutiny explains satisfactorily the matter of the supposed local origin of the lesions in carcinosis, about which so much is said, and claimed wrongly. We all acknowledge that cancer of the tongue and buccal cavity arise from the local irritation of a broken or decayed tooth, but of the thousands of such that exist, how very few result in cancer! Smoking, especially the use of a pipe, is accredited with cancer of the lip and mouth, but how seldom does this occur among the thousands who use tobacco! Cancer of the breast is often attributed to a blow, but almost every woman has, at some time, had a blow on the breast or irritation from a corset, while relatively few develop cancer. Stones in the urinary or gall-bladder are assigned as causes of cancer in those localities, but patients have been known to carry these for many years, even up to twenty-five, with no cancer resulting; as is also shown by hundreds of operations for their removal and the rare discovery of a cancer having developed. The same may be said of cancer in various other localities.

In regard to epithelioma of the skin, the epidermoid carcinoma of Ewing, upon which surgeons so often base their claim for radical operations, much may be said, but we forbear. If not irritated or treated wrongly this is often, or commonly a local, trivial affair, often easily cured in many ways, and only seldom, or when aggravated by injudicious treatment, does it manifest a destructive nature, and then it is owing to the same internal conditions which induce cancerous lesions elsewhere, as already intimated. We know how rarely metastases occur in basal-cell epithelioma, and very seldom in internal organs, but spinocellular epithelioma metastasizes freely, even in distant parts, as in the liver and bone marrow.

Applying now our simile of a mutiny of soldiers, to the action of the cells forming the lesion which we call cancer, we can readily see how a local irritation may act as the exciting cause of rebellion, by soldiers or cells, against existing conditions of life, while perhaps the latter alone would not suffice to produce a mutiny or the malignant growth: even as a spark suffices to start a great fire in combustible materials.

The soldiers may have endured their increasing discomforts and distress without resistance or mutiny, until some unjust or unkind treatment, or a blow, from a corporal or a sergeant, led them to open rebellion. In the same way the cells of a part may have long suffered nutritive and neurotic, or other grievances, and yet have striven to perform their functions faithfully, secreting milk, gastric juice, bile, urine, etc., until some external agency gave them a shock of unusual or unjust treatment. Some local injury precipitates matters and leads them to throw off their allegiance to physiological control and action, and starts them on their abnormal and riotous career. Ceasing to functionate as before in their proper glandular or other action, they still have the power of growth and reproduction, and a useless malignant neoplasm is formed.

We all know that after the surgical excision of an innocent adenoma, which had been pronounced non-malignant microscopically, true cancer may develop, metastasize, and destroy the patient; and the surgical removal of a true carcinoma will often seem to light up a much more severe and distressing trouble. It is quite logical to believe that, if the nutritional and other errors of system persist, these wild and riotous cells will continue their mad and destructive career, and that they will metastasize, as already mentioned. All this accounts well for the wrong theory of the purely local nature of cancer, which has gained such a wide acceptance.

All surgeons and pathologists claim that we know nothing of the true cause of cancer: but everything has a cause, and careful clinical study and experience now show abundantly the correctness of the doctrine of a constitutional origin and cause of carcinosis, and that when taken early the local lesions called cancer disappear and remain absent as long as the casual elements are kept under control. Diet, of course, is the basic element, in order that the cells may receive the proper pabulum with which to perform their duties. But perfect nutrition depends also upon the correct action of the various organs of the body, including the endocrinous glands, and hygienic and proper medicinal measures are often necessary to secure a perfectly healthy blood stream, from which the body cells receive their nourishment. When this is ideal, the cells have no cause to mutiny.

Late Recurrence in a Patient with Epidemic Encephalitis.—Rathery and Cambassades presented before the Paris Hospital Society a patient with a second attack of this affection. The first episode had occurred fifteen months before and was somewhat abortive in character. Eleven months after complete recovery there was a recrudesence with a Parkinsonian syndrome, salivation, exaggeration of reflexes, and foot clonus. Of interest was the fact that in the interval the patient conceived and bore a child.—*Gazette des Hôpitaux.*

SYNERGISTIC ANALGESIA WITH NITROUS OXIDE-OXYGEN AND MAGNESIUM SULPHATE.

BY JAMES T. GWATHMEY, M.D.,
NEW YORK,
AND
JAMES GREENOUGH, A.B., M.D.,
NEW YORK,
PRESBYTERIAN HOSPITAL.

STATISTICS, as well as laboratory and clinical data, demand the discontinuance of empirical methods of anesthesia, the using of some one agent or method because of its employment in some prominent clinic. American statistics,[1] embracing nearly 500,000 administrations, show that sequences and combinations are far more safe than any single method or agent. Laboratory experiments[2] prove that with preliminary medication the margin between complete anesthesia and respiratory arrest is lengthened, making anesthesia a safer procedure. Geoffrey Marshall[3] has shown that in severely shocked patients nitrous oxide-oxygen is not followed, as is ether, by a fall in blood pressure two to four hours after operation.

Pharmacologists are agreed that nitrous oxide is the least harmful of any of the general anesthetics in its effects upon the tissues and organs of the body. But nitrous oxide-oxygen, used alone, is immediately dangerous; when pushed to the point of saturation,[4] *i.e.*, when the patient is cyanosed, with dilated pupil and apnea, it is the most dangerous of all anesthetics. That patients have been asphyxiated and resuscitated does not warrant us in using this extremely dangerous method as a routine in order to avoid using ether, when the same results can be obtained by simpler and safer methods.

Meltzer and Auer[5] and their associates have proven that magnesium sulphate is not only an anesthetic, but also that it has no deleterious effect upon any of the tissues or organs of the body. Having proved fully its innocuous character, Meltzer made the natural mistake of attempting to use it *alone*, ignoring other agents and methods.

With all of the above and other collateral information we have attempted to avoid the mistakes of others and, taking advantage of the well-known synergistic action of all anesthetics and hypnotics, have used the most desirable in such a way as to get the greatest efficiency with the least risk. The three most desirable agents are, in our opinion, magnesium sulphate, morphine, and nitrous oxide-oxygen. By preliminary analgetizing the patient with magnesium sulphate and morphine and completing the analgesia with nitrous oxide and oxygen, the patient sinks into unconsciousness without struggling, is fully relaxed during the operation, and emerges from the ordeal without nausea, vomiting, or pain.

In the technique to be described in this paper, ether, chloroform, and ethyl chloride are absolutely excluded. Ether, by far the safest of these three drugs, is almost invariably followed by more or less nausea and vomiting, even when used with nitrous oxide and oxygen and in as small amounts as one to four drams. This does not hold when it is used intravenously or colonically. We can now get satisfactory relaxation without ether, and so this agent is entirely eliminated.

Studying synergistic analgesia from various angles and working in collaboration with many surgeons and anesthetists, several distinct techniques have been evolved, but in this paper only the technique for magnesium sulphate, morphine, nitrous oxide and oxygen will be considered.

To Dr. Adrien V. S. Lambert of the Presbyterian Hospital, New York City, more than to any one else, is due the credit for the development of the technique with nitrous oxide and oxygen. With this technique we have had between forty and fifty cases. The results have been so uniformly successful and compare so favorably with thousands of other cases in which nitrous oxide was used without the synergists that we have no hesitation in giving the full technique at this time, which is as follows:

Two soap-suds enemata one hour apart, or one soap-suds enema followed by a thorough irrigation until the return is clear, are given the night before the operation. A tap-water enema is given early the next morning. If not already in place, a folded sheet is placed under the patient to serve as a lifter at the proper time. The bed is now screened, if in a ward, or the room darkened and quiet demanded. Two hours before the operation a chloretone suppository, grs. xv, is given, after which the patient is not allowed to leave the bed. A half-hour later a breast hypodermoclysis is given of three or four hundred c.c. of a sterile and chemically pure 4 per cent. solution of magnesium sulphate at a temperature of 110° Fahrenheit. In one or two instances we have dissolved one tablet "A" novocain suprarenin in the solution and this seemed to allay the small amount of pain caused by the distention of the tissues. The whole procedure should be done aseptically, the solution running in by gravity in not less than thirty minutes. We have had no abscesses or sloughs.

A towel is now placed over the face, and every inducement is offered for sleep. The first hypodermic of morphine is given one and a half hours before the time set for the operation and consists of one-eighth of a grain. It may be given in plain water or magnesium sulphate. This is repeated at 15 or 20-minute intervals, until the full amount is given, the average adult receiving three-eighths of a grain. If an idiosyncrasy is present, it will develop before the time for the third dose. Quite often one-quarter of a grain is amply sufficient, especially for women.

At the proper time the patient should be lifted as gently and quietly as possible and placed upon the stretcher, or preferably upon the operating table, and taken to the operating room. Under no circumstances should he be allowed to help himself. When these precautions are taken, he will arrive in the operating room in a quiet and comfortable mood and quite often asleep. If asleep, he is probably analgesic, and in one or two instances the operation has been done by using novocaine for the skin and peritoneum.

However, our best results have been obtained by using nitrous oxide and oxygen. This factor may be considered as representing the margin of safety with this special technique, as it can be withdrawn

at any time, leaving the patient analgesic, but usually not unconscious. It is best to apply the mask before the usual preparation for the operation begins, as the gases themselves add considerably to the analgesia. With the mask in place, the oxygen is started at the same time as the nitrous oxide, and at no time should the patient be cyanosed or any attempt made to induce the usual signs of anesthesia. The patient, even before the inhalation of the gases, is almost completely analgetized, and the gases are used only to render the patient unconscious and to complete the analgesia. After the skin and peritoneum are incised, the oxygen may be rapidly increased up to 35 per cent., as the patient will be found fully relaxed, and stertor and cyanosis merely add to the danger without increasing efficiency. The second or excitement stage is absent, unless too low a percentage of oxygen is used and the patient becomes cyanosed. In certain cases, the gas and oxygen may be discontinued after the peritoneum is opened, but if rigidity is present, it should be immediately reapplied, and again during closure. A continuous administration with a high percentage of oxygen is the most satisfactory.

The general appearance of the patient in the condition just described (analgetized and unconscious) is so much more satisfactory than when the gases alone are used, that one feels fully compensated for the extra time and care taken in the preparation, and the patient's condition after the operation fully justifies every procedure. While some of the operations have been as severe as any known to surgery (including thoracotomies, removal of one or more ribs, decortication of lung, appendectomies, pylorectomies, gastrojejunostomy, jejunojejunostomy, tuberculosis of lungs and intestines, supravaginal hysterectomy, arteriosclerotic gangrene, etc., etc.), yet the symptom-complex known as shock is almost invariably absent. This does not mean that we can neglect the usual precautions when, from the nature of the operation and the low vitality of the patient, shock is expected.

An examination of the charts at the Presbyterian Hospital show that the respiration averages about 20. As respiratory arrest is the only factor to be feared with both magnesium sulphate and morphine, and as cyanosis is the one thing to be avoided with the gases; and as the respiration is normal and the patient is pink throughout—and, furthermore, as the patient is not in the third stage of anesthesia with consequent lowered blood pressure, but is analgetized and merely unconscious with normal blood pressure, it would seem that we have a more ideal condition in which to perform surgical operations than has heretofore prevailed.

Clinical experience, the final test of all medical and surgical procedures fully justifies this statement.

Wound pain is practically a thing of the past; the patients are comfortable for fifteen to thirty hours after the operation, with no nausea, no vomiting, and with respiration, pulse, and temperature about normal.

Where no great relaxation is required, or for minor operations or where for any reason it is impracticable to carry out the technique as described, the following modified technique has proved its value: One and a half hours before the operation, give by hypodermic $\frac{1}{8}$ grain of morphine in 2 c.c. of a chemically pure 25 per cent. solution, $MgSO_4$, and repeat in twenty minutes for a patient below par, and a third time for robust patients—making the maximum dose $\frac{3}{8}$ of a grain of morphine with possibly 1 100 grain of atropine and 6 c.c. of magnesium sulphate. This is to be supplemented by gas and oxygen—the oxygen to be started at the same time as the gas—the patient never to be cyanosed at any time, and the percentage of oxygen to be slightly increased over the usual amount after the operation has begun.

THE RECOGNITION AND CORRECTION OF ENTEROPTOSIS IN CHILDREN.*

By CHARLES GILMORE KERLEY, M.D.,

NEW YORK.

Children showing faulty growth and defective development along physical lines furnish us some of our most difficult cases. We often find such patients suffering from chronic gastrointestinal disorders which have resisted the usual method of management. Because of our inability to successfully cope with some of these patients and feeling that further information was a necessity, an *x*-ray study has been made in a series of 91 cases. The method of diagnosis heretofore had depended upon the symptomology, an examination of the stools, of the urine and of the blood. The treatment consisted in efforts in dietetics in the use of drugs, in rest cures and climate. By means of the *x*-ray carried out by Le Wald, we have demonstrated various types of abnormalities, congenital and acquired, that have enabled us to establish a correct appreciation of the condition, without which rational treatment was impossible.

Among the abnormalities found, only ptosis of the stomach or intestines or both will engage our attention. Children in whom we have proven enteroptosis are very similar in the following features: They show defective development, malnutrition, and secondary anemia.

The Ptosed Stomach.—We have no evidence to offer that this condition is of congenital origin. From a searching investigation of the previous feeding habits it would seem that in all our cases the ptosis may be explained by the overload, and this over-loading takes place during the first three years of life. The frequent feeding of 8 to 9 ounces in the bottle fed seems to be an important etiologic feature. Another and probably more important error is the custom in many families of forcing

*Read before the Medical Society of the County of New York, April 25, 1921.

large quantities of milk after a solid food diet had been instituted.

Ptosis of the Colon.—A complete colonic ptosis has always been associated with a ptosed stomach. Ptosis of the cæcum, however, we have observed in 5 cases in which there was no drop in the stomach, these also are in all probability a result of overloading and stasis, as there was a colonic deformity or angulation further on which caused the back-up.

As has been mentioned, the enteroptosis patient suffers from maldevelopment because of insufficient food intake, and this appears to depend upon the following chain of circumstances, namely: poor appetite, food residue, abnormal relations of the pylorus to the stomach, and hypomotility. All our cases in which a ptosed stomach was demonstrated showed food residue five hours or longer after a Bismuth meal. These observations have been corroborated by the use of the stomach tube after an ordinary meal. The ptosed stomach means an enlarged organ, a type of dilated stomach. All dilated stomachs with us have shown hypomotility.

The symptom complex enteroptosis in children is an habitually poor appetite, recurrent vomiting, nausea without vomiting, eructations of gas and constipation. These children are improperly nourished because of insufficient food intake.

The habitually poor appetite is due to the presence of residue in the stomach when the next meal hour arrives. In order for a child to be hungry at meal time there should be an interdigestive period of half an hour to an hour. In addition to the poor appetite the residue case is a subject of recurrent vomiting and has usually been treated for acidosis.

Ptosis of the colon and sigmoid invariably means constipation of a nature that requires daily attention to the bowel function. These patients are usually of the sway back type and the abdomen is enlarged.

Management.—Our first step is to secure proper mechanical support. An abdominal belt with a projecting ridge for those in whom the stomach alone is ptosed is fitted to the patient. The ridge is so arranged that the pressure is exerted against the lower portion of the stomach. In those in whom both the stomach and intestine are involved, a large thick pad is fashioned and attached to the inner surface of the belt. This support is worn constantly when awake.

Rest in a Recumbent Position.—The carrying requirements of the stomach are lessened and the emptying of the stomach is facilitated by having the child rest in a recumbent position (on the right side, if possible) for an hour after a meal, and only solids are given at meal time. Fluids such as milk and water are given at a period equally distant between meals.

Pyloric spasm, which we have frequently found in other abnormalities, has not been much in evidence in the ptosed stomach.

Constipation.—Our so-called constipation diet schedule is given the patient. Laxative doses of aromatic cascara are given three times daily in sufficient quantities to produce an evacuation. In some we have added nux vomica and belladonna. Daily massage by a skilled operator is employed if the family means will permit. The results of this management in the main have been satisfactory.

The improved appetite is readily produced by establishing a normal emptying of the stomach and a satisfactory gain in weight has followed the larger food intake. Later *x*-ray observations have shown the stomach occupying its normal relations. In those with the badly ptosed intestine the patients have not been observed sufficiently long to warrant conclusions.

(Several lantern slides demonstrating various types of ptosis were shown.)

132 WEST EIGHTY-FIRST STREET.

GONORRHEA IN WOMEN FROM THE STANDPOINT OF THE DIAGNOSTICIAN:

ITS COMPLICATIONS AND TREATMENT.

BY WARREN H. HOAK, M.D.,

BALTIMORE, MD.

P. A. SURGEON (R.), UNITED STATES PUBLIC HEALTH SERVICE.

POSSIBLY the greatest and most widespread of all venereal diseases in woman is gonorrhea, and there is probably no one infection which appears in so many varieties and forms, and is the etiological factor of so many and commonly met pelvic disorders, as this infection. And yet with the above known facts, its infinite variety of clinical pictures, its frequently obscure onset, its insidious progress, and the delicacy with which one must go about diagnosing the trouble if suspected, from a sociological point of view, often obscure the proper diagnosis and early treatment which is imperative if a cure without complications is to be obtained.

Now let us look into some of the factors which cause this disease to be so different in its extent, varieties, etc., from the same infection in man.

First of all, let us go back to the anatomy of the female genitalia—here we will remember that there is very close proximity of several structures, covered with mucous membrane, and glands, and *all* except the vagina affording an excellent culture medium for the development and extension upward into the pelvic organs—once the gonococcus is implanted. As a general thing all the external genitals as far as the cervix, including the urethra with the glands of Skene and Bartholin, which make excellent traps for the infection to lodge in, are found to contribute in the infection at the same time. Then, as the process extends, if not properly treated we find the infection traveling upward through the cervix, uterus, and tubes, and finally in some cases out into the peritoneal cavity. The process may not stop even in the peritoneum but may be blood-borne to various distant organs, as the several large joints, and serous cavities, as the pericardium and pleura and set up a very virulent and sometimes fatal inflammation.

On the other hand, gonorrhea practically always results from sexual intercourse, which in most cases is illicit (either directly, or indirectly on the part of the husband) and from the knowledge of this fact, the woman often tries to conceal her trouble —hide everything which, if she should make known, she fears would ruin her reputation and moral standing for life. Thus she does not seek medical advice early in her trouble, as she should, but allows it to continue until it extends to such an extent and her suffering is so great that she is *compelled* to seek

medical attention, and then often finds she has waited too long; that the process has gone far beyond a cure, and she sees invalidism and suffering staring her in the face for the rest of her life. Happily, however, this is not the fate of all women who transgress and are the victims of such an infection.

The sociological standing especially—the woman who has innocently become infected by her husband, must always be considered with the utmost acuteness. We must protect the social relations—not necessarily protecting the husband in his infidelity, but protecting the woman from knowing that she is suffering the results of an unfaithful husband, which would be much harder for her to endure than the suffering from the disease itself, and possibly break up an otherwise happy family relation with its sequential curses.

Another important factor which often causes delay in the innocent married woman is the fact that she is frequently led to believe that the discharge or burning sensation is only a physiological or normal occurrence, the result of early married relations, and thus she pays little or no attention to it until it advances to such an extent as to cause her unbearable suffering, when she decides to consult her physician—and here, again, the latter may not be alert, and not suspecting the true nature of the infection, assures the patient there is nothing to be alarmed at, and administers symptomatic treatment without seeking the cause of the malady and removing it if possible. Thus the physician who undertakes the care of a woman with a suspected gonorrhea has no easy task on his hands. It will require every bit of skill that he possesses both in determining the true nature of it, and afterwards in the handling and treatment of the case.

The popular question might easily come up here: "Can you cure a case of gonorrhea in the female" and if so what would you be guided by in giving a favorable prognosis?

This is a greatly disputed question and the answers will vary possibly in almost direct proportion to the number of men you question on the matter. For instance, should you inquire from an obstetrician he would undoubtedly say—"Once a woman contracts gonorrhea, she always has it although it may cause no marked symptoms, but generally if she becomes pregnant she always tends to run more or less of a temperature during her puerperium which as a general thing does not prove serious, but at the same time is supposed to be the result of the old infection, that is, of course, providing there is no other causing factor. Be on the lookout for this during the puerperium of such women.

On the other hand—a gynecologist would be likely to tell you that gonorrhea is curable providing the case is seen before it extends beyond the internal os, and proper treatment is administered at once and faithfully carried out. However this unfortunately is not always the case, as one would readily deduct from gynecological statistics, which show the great percentage of women suffering from acute pelvic disorders, 90 per cent. of which are supposed to be due to gonorrhea. Thus in all suspected cases be guided by your better judgment rather than the social standing of your patient, in giving your prognosis and making your diagnosis.

Now that we have dealt with some of the many obstacles with which the physician meets in determining the true nature of this trouble, and have spoken of the necessity of an early and proper diagnosis with appropriate treatment before the process travels into deeper structures beyond medical aid, let us consider some of the common complications which result from neglected and improperly treated cases of gonorrhea.

As we know, the complications of this disease in the female are numerous, and volumes have been written on the subject. It is not my intention here, however, to consider the entire list, neither do I intend going into the finer details of any one complication. I merely intend considering briefly the important points of some of the most common complications which the physician is constantly coming in contact with, and if he is not on the alert will often baffle him.

In considering the complications of this disease we shall speak first of the parts primarily affected in which the affection may go on to a chronic process, thence the extension upward to pelvic structure.

As I mentioned before, due to the close proximity of the external genitalia, as the vulva, urethra, with their glands, vagina, etc., when once the gonococcus becomes implanted it generally attacks all of the structures at about the same time—and the result is an acute or subacute vulvitis, urethritis, or vaginitis. When this occurs we find these parts greatly inflamed and more or less edematous. The vulva, urethra, and vagina are swollen, red, and very tender, presenting the cardinal signs of inflammation as found elsewhere, and bathed in a creamy purulent exudate. This process tends to become chronic and the glands of Bartholin often become the seat of abscess formation. They are seen to be swollen, red, and tender, and fluctuation may be present. On incision we find them filled with a creamy pus, rich in gonococci. Skene's glands of the urethra are often found in the same condition and if not properly treated in the same manner are frequently the cause of a long-standing and chronic inflammation with extension upwards to the tubes and ovaries, due to the fact that the germs are lodged deep in the tissue of the glands and are not reached by the ordinary and common irrigation and application to the surrounding parts.

A specific cystitis often results; due in most cases to improper catherization and irrigation, although it may extend by tissue continuity through an infected urethra. This is a common occurrence, especially in the female, and the damage does not always stop here, but may extend by way of the ureters to the kidney and result in the development of a gonorrheal pyelitis.

Gonorrheal endocervicitis is thought by many men to be the primary seat of infection and the others secondary, but this can hardly apply to most cases. It is frequently the result of a neglected or improperly treated vulvitis and vaginitis, due in many cases to improper manipulation and irrigation on the part of doctor or patient, but in some cases it may be the result of extension by continuity of tissues. While this is a very grave complication in any case, due to the chance of extension up into the uterus, the prognosis must always be guided by the relation of the process to the internal os. Once it passes this limit, the woman is past a cure by

medical means, in the opinion of our best authorities of to-day.

This condition should, however, be readily recognized and treated before further extension takes place. It manifests itself by a thick tenacious secretion (white of egg) which is always characteristic of a cervical discharge, while that from the uterus, on the other hand, is thin in consistency and of a milky appearance. The cervical secretion is quite irritating, and if the process is an acute one, it will contain the gonococcus. The cervix is found to be greatly swollen, tender, edematous, and bleeds readily on manipulation.

This condition, if neglected or improperly treated, tends in all cases to run a chronic course and extend up into the endometrium, continuing its work there. It can readily be differentiated from a chronic endocervicitis or malignancy of the cervix by its short duration and acute onset and from an endometritis by the nature of the discharge; and whether or not it is gonorrheal in character is determined by a microscopic examination or the history of a previous existing gonorrheal vulvitis or vaginitis.

While it is not the consensus of opinion that a cervicitis is the cause of the infection of all the parts lower down as the vulva, urethra, etc., it is, however, with metritis probably the cause of a chronic vaginitis, due to the fact that the vagina is not a favorable seat for the germ to live. When found in this place it is probably due to the constant presence of the cervical or uterine discharge, which is full of the germs, thus causing a constant infection and chronic inflammation. Once the cervical infection becomes chronic we have a sad state of affairs, and the process by this time either has extended or is extending upward into the endometrium and on to the adjacent structures.

Next in anatomical order as the process extends upward we have the involvement of the endometrium. The gonococcus is by far the most frequent source of bacterial infection of the unpregnant or non-puerperal uterus, due to the fact that it is about the only germ that will implant itself and grow in the tissues on mere contact. Once the infection passes the limits of the internal os we have an endometritis to deal with. This may come about by a spontaneous extension upward by continuity of tissues or as the result of improper manipulation of the parts with applications, irrigations, etc.

The endometritis may occur immediately after the infection of the cervix, or the inflammation may remain localized in the latter for weeks or months, but during the menstrual period is the most favorable time for spontaneous extension upward, due to the condition of the tissues at this time. Once the gonococcus is implanted on the endometrium it tends to spread and involve the entire lining of the uterus. It may be found through the tissues of the uterine walls, although more abundantly in the mucous membrane and deep in its glands. This condition manifests itself by the usual signs of acute inflammation elsewhere; the uterus is congested, swollen, painful, and tender to the touch and a mucopurulent (thin) discharge is seen to exude from the cervix, which will show on microscopic examination, dead leucocytes, epithelia, pus, and a few red blood corpuscles with an abundance of the diplococcus of Neisser.

This generally comes on some few weeks after the vaginitis and cervicitis, and its course is always progressive, tending to become chronic with further extension upward and involvement of the tubes with a resulting gonorrheal salpingitis with extension to ovaries and adjacent peritoneal surfaces; but it does not involve the connective tissue (parametrium) to any great extent thus differing from the ordinary pus organisms.

Now let us follow the infection on to the tubes. This possibly is one of the most common and disastrous complications of gonorrhea in the female, causing invalidism and sterility, in many cases, for the rest of the woman's life, providing the process is a bilateral one, as it generally is. Statistics show that the greater number of cases of acute pyosalpinx are due to gonorrheal infection and that it is the etiological factor in practically 80 per cent. of all chronic inflammatory masses of the pelvis. Pyosalpinx is said to be the characteristic lesion of pelvic gonorrhea.

The process in the tubes follows on closely after the infection of the endometrium and may be detected either in a few weeks or months after the endometritis has been established. In many cases of an unrecognized gonorrheal infection of the organs lower down we may have the inflammation arising apparently spontaneously, with very severe symptoms. In these cases we must inquire into the history of a previously existing urethritis or frequent urination with burning, etc., and at the same time examine a smear from the cervical discharge. Such cases as these are often found in young women who have been married but a few months and come to the physician complaining of marked pain and tenderness in the pelvis over the tubes, with rigidity of abdominal muscles, backache, headache, and general malaise. In these cases we generally get some fever (102°-104°) and a pulse invariably much faster in proportion to the temperature.

The uterus is found to be enlarged and softer than normal, very tender, and boggy to the touch. The intense edema of the surrounding tissues make it practically impossible to palpate the tubes. The pelvic structures are pushed low down in the cul-de-sac and the latter is found to contain a purulent fluid which harbors the diplococci. When the tubes are exposed to the eye they are quite characteristic of Neisserian infection causing the trouble, being markedly swollen, congested, edematous, and full of pus. Their ends are inverted and adhesions to surrounding parts are often present in contradistinction to tubercular tubes which are not tied down by adhesions and whose ends are always everted resembling that of a cock's comb.

This condition tends to run a chronic course with extension to the ovaries resulting in a chronic salpingitis and oophoritis which will, in most cases, continue with relapses and remissions throughout the sexual life of the woman until the menopause when the parts atrophy and the process subsides.

It may be well to mention here in regard to the diagnosis from examination of the contained pus, that the gonococcus is not always found in pus of a long-standing pyosalpinx, due to the fact that it is a short-lived coccus, and that it dies after a certain period of time in its own secretion.

Treatment.—In considering the treatment of gonorrhea and its complications we will divide it into two parts, namely *prophylactic* and *curative*.

The prophylactic is possibly as much if not more important than the curative, because upon it depends to a great extent the final result as well as guarding the patient from carrying the infection to more distant parts of her own body, as the eyes, etc., and also affording protection to other members of her family from infection.

When a woman with a specific infection of the genitalia consults a physician she should be instructed at once regarding the very infectious nature of the disease, warning her at the same time of the disastrous results it may lead to, both to herself and the others who come in contact with her, if she does not carry out the rules set down for her. In other words she should be instructed how to live until the infection has been eradicated from her system. In many cases of married women who are innocent of the nature of their malady these strict instructions will often arouse their curiosity and they will ask the cause of their trouble. In most cases it is not wise to make the truth known, especially if it is going to bring about a break in marital relations, and the physician can in most cases eradicate this tendency by telling the patient that she has a very virulent infection, the secretion from which is quite prone to infect others as well as herself, with special explanation regarding the infection.

Instructions to the woman regarding the care of herself and mode of living should be somewhat as follows: In the very acute cases she should be kept in bed. She should refrain from any violent exercise as horseback riding, tennis, dancing, heavy work, etc. Her diet should be of a mild nature, and she should refrain from stimulating foods, as condiments, alcoholics, etc. She should use separate toilet linen, basins, etc., and her hands should be washed in a solution of bichloride of mercury each time after she touches the infected parts—with special instructions again regarding her eyes. All packs, sponges, bandages, etc., should be burned at once, and needless to say cohabitation should at all times be refrained from.

The *curative* treatment varies greatly with the different physicians handling the disease, but in all modes of treatment the purposes are about the same, namely: 1. To prevent upward extension. (2) To relieve the discomfort. (3) To eradicate the infection completely.

In considering this part of the treatment we will include all the external genitalia as far as the cervix with urethra and its glands, as all of these structures are generally involved to a greater or less extent at the same time, and then we will take up the complications individually.

Possibly the best way to handle the cases is to follow some routine schedule, modifying the treatment, of course, for each individual case as it presents itself. For convenience this may be divided into the *treatment by the doctor at the office*, and the *home treatment as prescribed by him*.

For instance a patient consults the physician with a case of acute gonorrhea involving the vulva, vagina, and vaginal surface of the cervix.

The patient should be put on the table in the lithotomy position, her parts thoroughly flushed out with some mild antiseptic solution and then examined, care being taken not to carry the infection further up into the cervix. Now after the parts are thoroughly cleansed they are painted over with some silver solution such as a 5 per cent silver nitrate or 25 per cent. argyrol solution and dusted with boric acid or packed with sterile gauze which may or may not be glycerinated to prevent adhesions. The strength of these solutions may be increased up to 40 per cent. in the vulva and vagina if the parts will stand it. The application is best done under gas anesthesia. In the urethra we should not use a solution stronger than 5 per cent. because of the sensitiveness of the structures. This should be applied after the urethra has been thoroughly irrigated by means of an applicator through the urethral tube.

If the external os is open and the infection has not extended through it, it may be packed with gauze soaked in a 20 per cent. solution of silvol which is allowed to remain there 24 hours to prevent upward extension, when it should be removed and replaced again by the physician.

The use of iodine in the form of an iodex pessary tamponed with cotton every other day, allowed to remain twenty-four hours, has proved beneficial in chronic stages where there is an extension to the tubes.

The patient should now be sent home and instructed to irrigate the parts freely with a slow return flowing irrigator, using at least a gallon of some hot mild antiseptic solution at each time. This solution may be a two or three per cent. carbolic or bichloride of mercury (1-10,000) and should be used at least three times daily.

IRON AS A GROWTH FACTOR IN INFANCY.

By LOUIS BERMAN, M.D.,

NEW YORK.

RECENT studies of the nutrition of young growing animals by means of synthetic diets have emphasized the importance of different food elements and constituents as growth factors. It has been shown that out of the thousand or more different substances found in the animal and plant foods the animal feeds upon there are necessary, in order to obtain satisfactory growth and health, a sufficient minimum quantity of at least sixteen amino-acids, the carbohydrate glucose or one of its polysaccharides, at least nine inorganic elements: sodium, potassium, chlorine, iodine, calcium, magnesium, phosphorus, iron, and sulphur, and the vitamines fat-soluble A, water-soluble B, and water-soluble C. All of these growth factors are present in the milk offered by the properly fed healthy mother to the suckling in the right proportions except iron.

Even under the most ideal of conditions, breast milk, cow's milk, goat's milk, and the other animal milks analyzed by the physiological chemist contain but traces of iron. Bunge was the first to stress the significance of the relatively small amount of iron in milk ash. He compared the composition of the ash of milk with that of new-born animals of the same species, and showed that, while the other inorganic elements, sodium, potassium, calcium, and so on, were present in nearly the same relative

proportions, there was six times as much iron in the organism of the young animal as in that of the milk on which it was nourished. It followed that there must be at birth a reserve of iron in the suckling from which it could draw its supply for growth and to increase the amount of hemoglobin of its blood to keep pace with its increasing mass, besides making up for what it lost.

Certain results of chemical analyses of the organs confirm this assumption. The percentage of iron in the entire organism is highest at birth. During the suckling period the amount of iron in the normal remains constant, although the body weight increases constantly, as well as the amount of total hemoglobin. In other words, the reserve iron is converted into hemoglobin iron, or other forms necessary, and so the iron balance of the organism is maintained.

The amount of iron present at birth in the organism is three times as much as in that of maturity. How does this occur? The researches of Bunge, Hugouneng, and others, proved that the amount of the inorganic elements fixed by the fetus in the last three months of pregnancy is twice as great as that fixed in the first six months. This applies also to iron. But as the amount of iron to begin with is greater, the percentage at birth is six times as great as the other inorganic constituents. Most of the reserve iron is deposited in the liver.

This storing up of iron is accompanied by a decrease of iron in the body of the mother. That has been proved in the guinea-pig by Charrin and Levaditi, and probably accounts for the predisposition of the mother to anemia during pregnancy. This storage of excess iron in the fetus at birth, it may be assumed, is provided in order to make up for the lack of iron in the mother's milk.

If the amount of iron at birth is three times as great as at maturity, and there is a constant total iron, as Bunge showed, the percentage of iron, that is the amount distributed throughout the organism, will become about that of maturity when the birth weight is tripled. This is what occurs at about one year. At this time other iron-richer foods than milk are added to the food of the infant. We see in both the qualitative and quantitative iron relations of mother, milk, and infant, a mechanism of nature for guarding against iron deficiency in growth as a matter of prime importance. That this has been worked out for iron alone probably depends upon its enormous importance both in the provision of hemoglobin for the proper oxygen supply to the cells and its role in intracellular oxidations.

Much remains to be cleared up concerning the role of iron in metabolism. It certainly is important as the oxygen-retaining portion of the hemoglobin molecule, fundamental therefore as a carrier of oxygen for intracellular respiration. But it has also been shown by Spitzer that the oxidizing enzymes, the oxidases in cells, are always associated with the iron-containing constituent of the nucleus. Iron regularly accompanies nucleins and nucleoproteins wherever they are found. In organs of greater oxidation more iron is found than elsewhere. Thus there is 0.02 per cent. in the liver and 0.01 per cent. in heart muscle, less in other muscles. Its position as an oxygen carrier and intracellular oxidation catalyst establishes its importance as a growth factor in infancy.

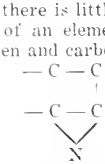
Effect of Deficiency of Iron.—It follows from the above considerations that if there should be a deficiency of the reserve iron to begin with, or an increased loss during the suckling period, or a failure to supply iron from without when the iron reserve disappears, *i. e.*, at about one year, certain effects upon the character of the blood and of intracellular oxidations, *i. e.*, growth, should become manifest. As a matter of fact, both of these disturbances, an anemia and failure to grow, have been observed following one of these three causes of iron deficiency in an organism.

As might be expected, the type of anemia observed has been that resulting from an interference with the formation of hemoglobin, the so-called chlorotic type, from the resemblance of the blood picture, a low color index associated with a fairly normal number of red blood cells, to that of the chlorosis long known to occur in girls at puberty. This chlorotic anemia, it is conceivable, may occur as a result of insufficient iron reserve in the liver. So it is observed regularly in twins, who have to share the mother's iron between them, and so are born into the world with only half the iron they ought to have; in premature infants, who being born before term, have not lived sufficiently long in the uterus to be supplied with the total amount of iron to which they are entitled; *e. g.*, if born at the eighth month there will be 22 per cent. less of iron laid down in the liver than if delivered at term. To a less extent, the same applies to infants born with a low birth weight who may be assumed to be premature to that extent. A deficiency of the mother in iron could also account for a low iron reserve in an apparently normal infant at birth.

So much for the congenital deficiencies in the iron reserve. Such deficiencies may also be acquired. Ninety per cent. of the daily loss of iron from the body is by way of the colon. In certain cases of colitis in infancy, long continued, a great deal of iron may be so lost, because more iron is excreted by the irritated mucous membrane, and the iron reserve may thus be depleted. One thus sees a chlorotic anemia developing in infants with a normal family and birth history who have suffered a long time from a colitis. Besides this, keeping an infant upon a milk, *i. e.*, iron-poor, diet after the first year will result in the production of a negative iron balance and a consequent chlorotic type of anemia.

Not that every instance of chlorotic anemia in infancy must necessarily be traced to such a deficiency of the iron reserve. For into the construction of the hemoglobin molecule more factors enter than the iron content of the liver. In the first place there are the internal secretions which control the normal functioning of the bone marrow. Hemoglobin consists of globin, a histone protein precipitated by ammonia (for the formation of which a large amount of the diamino-acid histidin, not present in milk, is necessary), and the iron-containing pigment, hematin. Before hematin can be formed it is necessary that there be supplied the pyrrhol ring containing substances which are its nucleus, and which the animal organism cannot synthesize.

This pyrrhol ring, which is present in the amino-acids, prolin, oxyprolin, glutaminic acid, and tryptophan, of which there is little in the milk proteins, is just as much of an elementary requirement of animals as nitrogen and carbon itself, for lacking it



they will starve. The ring is contained in small amount in most proteins, and is an important component of chlorophyl, the green coloring matter of plants. Although chlorophyl is not digested by the intestinal juice, it may be split up by intestinal bacteria, and thus made available for absorption. In short the history of hemoglobin formation is complex, consisting of a series of events, a disturbance of anyone of which will result in anemia. Nevertheless, evidence points to the iron factor as by far the most frequent and important in the production of the chlorotic anemia of infancy.

At birth about 40 per cent. of the total body iron is held as hemoglobin. As the infant grows the amount of hemoglobin increases, the non-hemoglobin iron decreases. Also, the reserve iron in the liver decreases. It follows that the source of the iron in the new-formed hemoglobin is the reserve iron which agrees with the facts already stated concerning the function of the reserve iron mechanism.

Iron in inorganic form has been used for centuries in the treatment of anemia. With the introduction of experimental methods controversy developed concerning the ability of the organism to utilize inorganic iron and the relative merits of organic and inorganic iron. Most of the experimental work done is valueless because no cognizance was taken of the importance of other food and growth factors as they affect nutrition and hemoglobin metabolism. This explains a good many of the contradictory results obtained. There are no experiments on record of a diet complete in every respect except as regards its iron content. Workers in the field of nutrition, however, now hold that inorganic iron may supply the organism's need of iron as much as inorganic calcium will supply its need of lime. Thus Osborne and Mendel, in their standard salt mixture, a mixture of inorganic salts intended to satisfy the inorganic needs of the organism, use iron in the form of ferric citrate. McCollum in his book on the Newer Knowledge of Nutrition states that the iron present in drinking water "aids in some degree in preventing iron starvation in the infant," and also that "milk is therefore capable of nourishing the pig during many, many months, with no other modification or additions other than the addition of small amounts of iron," citing the case of a pig brought up on milk alone up to the reproductive age, and states that "there can be no doubt that the milk which she consumed was enriched to some extent with iron by being in contact with cans having part of the surface free from tin. City drinking water also was furnished, and this contained appreciable amounts of iron." In short, it is recognized that iron is a growth factor, that its minimum quantity in a diet is necessary to growth, and that inorganic iron may act as the sole source of iron in a diet.

In feeding the human infant up to the first year conditions would appear to be ideal for the settlement of the question. The milk or milk modifications fed contain all the necessary growth factors except iron. If there should be a deficiency of the normal reserve iron in the liver, as occurs in twins, prematures, low birth weight babies, and in those who have suffered from certain types of colitis, the effect of inorganic iron should be manifest and measurable. In this connection, however, it should be pointed out that not only does the reserve iron play a part in this anemia, but that also the state in which the iron is offered plays a role in determining whether or not it is to be utilized by the body. Thus the analyses of Krasnorgorsky showed that the iron in human milk is more easily retained than that of the milk of any other animals, *e. g.*, as compared with goat's milk four times as much relatively of the iron of human milk is retained. Besides, human milk contains about three or four times as much iron as cow's milk (4 mgm. per litre) and Soxhlet demonstrated that this was quite enough to satisfy the demands of the infant. Yet even in the breast fed the amount of iron gradually diminishes toward the latter periods of lactation and hence prolonged breast feeding is liable to cause anemia. It should be emphasized also that the chlorotic anemia of infancy may be observed at any time in the breast feeding period.

An interesting point relating to growth appears to divide the cases of the chlorotic anemia of infancy into two classes: one in which there is anemia of the oligochromemic type with or without pallor, and adequate layer of subcutaneous fat, firm tissues, and no apparent disturbance of growth; in the other class growth has ceased, the weight is stationary and below the average, the color is grayish or waxy or yellowish white, and the tissues are flabby. Those of this latter class are also weak and have frequent colds.

In a series of twelve cases, including two sets of twins, observed in private practice, periodic examinations of the hemoglobin and iron content of the blood as well as of the weight were made. These showed in all cases a resumption of growth with a return of the hemoglobin and iron content of the blood to the normal when inorganic iron was fed in relatively large amounts. No changes were made of the formulas upon which these infants had remained stationary in weight and increased the poverty of their blood in the hemoglobin. The details, including the charts showing the iron hemoglobin and weight curves, will be presented elsewhere. They showed definitely that inorganic iron is a growth factor which may be observed as such and influences the entire nutrition of growth of the infant. In the case of some of them it had been attempted to relieve the condition by supplying the iron in the form of beef juice, orange juice, egg, oatmeal, and vegetable purées, but without result. It is not possible to conclude whether this ineffectiveness of iron present in these foods was due to its unavailability to the organism as such or whether it should be put down to the relatively small quantity present as far as these individuals were concerned. It is possible that the provision of iron in large quantities has the effect of accelerating a reaction in quasi-catalytic fashion, following the

physicochemical law of mass-action, according to which a reaction proceeds at a velocity proportional to the mass of the substances taking part in the reaction. Accordingly, much of the iron ingested is excreted in the stools. But the effect upon the growth curve and the hemoglobin and iron content of the blood is obtained just the same. If iron is fed in small amounts, not sufficient to appear macroscopically in the stools, the effect is not obtained.

The work of Abderhalden, who produced acquired form of the chlorotic anemia of sucklings in animals by prolonged feeding of new-born upon milk, showed that the condition could be cured by the introduction of inorganic iron salts. In the words of Osborne and Mandel, "The fact that the growing animal can fully supply from inorganic sources its requirements for the elements specially discussed in this paper emphasizes anew that it is unnecessary to consider the presence of calcium, phosphorus and iron, for example, in natural foods to the degree that is currently believed. Any shortage of an essential inorganic element can be suitably remedied . . . . by the use of its salts."

ETIOLOGY AND TREATMENT OF GASTRIC HYPERACIDITY.

BY JOSEPH KATZ, PH.G., M.D.,

NEW YORK.

INSTRUCTOR IN MEDICINE AT THE NEW YORK POST-GRADUATE HOSPITAL.

AT a recent gathering of medical men the question was raised as to the treatment of hyperacid cases with heartburn and sour mouths. Most of the men present confessed the unsatisfactory results obtained at their hands with the treatments they had tried. I shall therefore try to discuss the subject from a gastroenterologic standpoint and outline a routine treatment which has been successful in my hands in a good number of these cases.

In considering treatment of any pathological condition or even physiological abnormal development, the most important is to know the cause, if possible, and upon removal of the cause the major part of the treatment has been accomplished, there remaining only to treat the complications resulting therefrom. The causes of hyperacidity are very numerous and I shall discuss, as briefly as possible, only the more common of them, as follows:

1. All neurological conditions, including all neuroses and more severe types of mental disturbances. In these cases belladonna and alkalies will not benefit the patient, but the treatment or alleviation of the actual condition will in turn relieve the hyperacidity.

2. Visual disturbances of any kind will in the majority of cases if prolonged, although unnoticed by the patient but found on examination, cause hyperacidity and the only remedy or cure is to correct the actual condition, when all other medication and diets will not relieve it.

3. Nasal obstructions, mouth breathing causes dryness of the mouth irritating the mucous membrane of the esophagus (besides that it may cause laryngeal and bronchial disturbances), reflexly setting up hyperstimulation of the gastric mucous membrane followed by hypersecretion and hyperacidity. The remedy is self-evident.

4. Defective teeth may be responsible for a good many gastric disturbances and among those hyperacidity, yet this does not justify the extraction of teeth in all cases as has been the fad in the last few years. The innocent teeth are blamed for the ignorance of the diagnosticians being a close second to their fellow brother or sister the appendix. The so-called gold and silver mouths, gold caps, fillings, and gold plates are greatly responsible for hyperacidity of the mouth.

5. Hypothyroidism. In my article on "Deficient Thyroid Secretion as an Etiological Factor in Gastric and Duodenal Ulcers and in Hyperacid Conditions" (Medical Record, May 29, 1920), I pointed out the rôle that lack of thyroid secretion may play in causing hyperacidity. The treatment then narrows down to one point, namely, the artificial supply of thyroid.

6. Cardiac disturbances may cause any gastroenteric condition and in a good many cases hyperacidity, sometimes overtreatment with digitalis, may bring on hyperacidity.

7. Toxemias of every kind, and especially of the influenza type, are often etiological factors. Who did and does not see the after effects of the last influenza epidemic and its deplorable results, especially regarding psychoses of various degrees and gastroenteric disturbances with a great number of hyperacid cases predominating. In these cases restorative treatment, good food, pleasant surroundings, and change of climate will clear up most of the cases.

8. Disturbances of the gastroenteric proper as hypersecretions, ulcers, gastritis, appendicitis, colitis, enteritis, and their combinations. This class of cases requires rigid treatment, but I shall not enter into the discussion of that at present.

9. Gall-bladder disturbances, as cholelithiasis and cholecystitis, will cause hyperacidity. Their treatment will not be discussed here.

10. Various nephritic disturbances and also diabetes mellitus, whether pancreatic or nephritic, will bring on hyperacidity even in the early cases.

11. Pathological conditions of the organs of reproduction in females will in a great number of cases cause hyperacidity, especially in the pathology of the cervix, as it has been pointed out by the author in his article, "Pathological Conditions of the Organs of Reproduction in the Female Causing and Simulating Gastroenteric Disturbances" (MEDICAL RECORD, February 5, 1921).

12. Sexual disturbances and perversions; un-

gratified sexual stimuli, especially so in unmarried men and women, usually resulting in nervousness, headache, and heartburn with constipation, while on the other hand excesses in sexual indulgence bring on nausea, headache, hyperacidity, and most of the time diarrhea; the same is true, of course, of masturbation.

13. The hyperacidity of pregnancy is well known to all medical men, its treatment is sometimes rather easy, at other times will yield to no medication even in the nontoxic cases. The general routine treatment which will relieve the hyperacid condition in most of the cases I shall speak of later in my paper.

14. The quality, quantity, and kind of foods. As a rule heavy meat eaters will at some time complain of hyperacidity which may even lead to more serious organic disturbances. Those that indulge in spiced foods in great bulk or highly seasoned foods and vegetables will in time bring on hyperacidity. Smoked fish and canned foods will cause hyperacidity in a large percentage of cases. Constant indulgence in highly sweetened food, and especially those who constantly partake of it on full stomach, will cause hyperacidity.

15. Drugs. It is a well-known fact that some drugs, as the salicylate group, phenacetine, acetanilide, etc., will cause in certain people a high acid condition.

16. Night work or keeping late hours will in time result in hyperacidity.

17. Great indulgence in tea, coffee, alcoholic beverages, tobacco, and other stimulants may cause hyperacidity.

18. Recently another form of hyperacidity has been found in those that are following the latest fad of yeast chewing, and even physicians have fallen victims to this habit, not knowing its effects. I have seen dozens of cases during the so-called yeast campaign suffering with hyperacidity, belching, and fulness in the epigastrium after meals and complete distress instead of relief. Its use has no physiological basis, and it has no curative effect on the gastroenteric tract.

19. Excitement of any kind, whether joy or sorrow, will bring on high acidity.

Having thus enumerated the most frequent causes of gastric hyperacidity I shall now enter into the discussion of the general treatment and the first thing to do is to remove the causative factor, if possible; then regulate the mode of living and hygienic surroundings, next regulate the diet. The following has been very helpful in most of the hyperacid cases.

Small, frequent meals of nonirritating food. Let the patient have a vegetable, milk liquid diet. No meat of any form or kind nor its extracts as beef juices and soups; no spiced or highly seasoned foods, no condiments of any kind, no sweets in any form; no tea or coffee, no alcoholic beverages of any kind or make (complying strictly with the 18th amendment in its full text); no cold or carbonated drinks on the market, especially the sweetened kind; no smoking. In using milk or soups the quantity should not exceed a glass at a time, but at frequent intervals. Eggs soft boiled, preferably one at a meal.

Alkaline mouth washes should be used after each meal. The bowels should be kept open with some saline laxative, as artificial Carlsbad salt, the sal carolini factitium, N. F.

Belladonna or its alkaloid atropine given at first in large doses until its full effect is brought about should be given. And here I would caution against prescribing this drug for patients with an idiosyncracy or for pregnant or nursing women. After obtaining the full effect of the drug the dose is cut one-half. Always one should add some alkaline substance to it, as milk of magnesia in large doses before meals, giving some different alkaline after meals.

Gastric alkaline lavages every day at first and then on alternating days will materially aid in bringing about good results. The above outlined treatment must be continued for a long while, but by perseverance it will be found positive and permanent.

616 MADISON AVENUE.

AN EPIDEMIC OF MEASLES AT AN INDIAN AGENCY.

BY EDWARD RICE, M.D.,

KELSEYVILLE, CALIF.

FORMERLY PHYSICIAN TO THE STIKINE INDIAN AGENCY.

In the course of several years with the Indians at the Stikine Indian Agency in the northern part of British Columbia one experiences a number of incidences which afford a few facts worthy of mention.

The Indian of this locality is of the inland type; a few still retain the "face and frame" of the Plains Indian but on the whole a large majority, after much intermingling, have lost the characteristic caste and are more or less of a mongrel type. The Indians close to the Agency have advanced in civilization to a noticeable degree but those in the interior are largely still primitive in nature, methods, and superstitions. The medicine man is still a dominant figure during sickness, with his gong and dance, lizard legs, weird decoctions, etc., and is generally successful in removing "a frog from the head" or "an otter from the bowel." But I am not prepared to say just why such diseases as measles and the care of accidents during parturition are passed up to the white doctors for attention.

A recent epidemic of measles among these Indians totaled 177 cases. The disease ran the regular course in so far as the catarrhal symptoms and the eruption were concerned but with greater severity in Indians than in whites. The eruption first appeared in the throat before constitutional symptoms were manifested. During the epidemic seven cases occurred in the whites by which the comparative effects on the two races could be noted.

The period of incubation appeared to be about the same, about 10 days. The eruption in the throat preceded the general symptoms of invasion about three days and disappeared before the rash became evident on the face. In the Indian the rash spread to the body much more rapidly than in the white and in many cases the entire body was involved in from 36 to 48 hours. The skin was uniformly

thickened but with no edema and the eruption appeared to mass, not just mottle with clear skin between the mottles, but huge areas covering an entire side, and in some instances the entire body, were involved with no intervening clear space. The temperature ran high; in most cases over 104°, and in three reached 106°. Gastrointestinal disturbances were present in every case from the start. The eruption and temperature subsided by crisis rather than by lysis; often in 24 hours the temperature dropped to normal or nearly so and the eruption noticeably faded.

The duration of the disease from the early throat signs to the disappearance of the rash was about ten days. The time required for the desquamation to be completed varied owing to the fact of the natives being rather lax in the matter of personal cleanliness. The age seemed to play no important part in the manifestations; the young and the old suffered alike, and the age limits were from 2 years up to 80 and over, with fully four-fifths of the cases among adults. One boy, aged about 19 contracted the disease a second time during the epidemic and one woman, aged about 35, gave a history of having had measles 12 years before at Hazelton.

Eight women were pregnant at the time. Four showed signs of aborting and were in the fifth month of gestation. Of these two responded to sedative treatment and the accident was avoided, the gestation going on to uneventful full term. The other two aborted what appeared to be five month fetuses, neither of which showed any signs of eruption. In two other cases gestation proceeded with no disturbance and terminated later normally. In the seventh, a woman with the rash fully developed gave birth to a healthy boy baby at full term. This baby showed no signs of measles at birth nor did it subsequently develop measles although nursing from the mother while the mother was still in eruption. An eighth pregnant woman gave birth at the seventh month to a boy baby weighing 4½ pounds. This baby was poorly nourished and marasmic and died 59 days after birth.

Catarrhal pneumonia developed in one case with fatal results, this being the only death in adults during the epidemic; two other deaths were reported in old persons at outside localities, but the cause of death was not stated. One case appeared to be of the hemorrhagic form with great prostration and recovery was much prolonged. It was clearly more than simply a case of hyperpigmentation.

The treatment consisted mainly in the use of calcium sulphide in half-grain doses. I am convinced that this remedy has a salutary effect in measles. In cases already advanced its use affords prompt relief of the catarrhal symptoms and disagreeable cutaneous irritability and also appears to shorten the course of the disease, lessen the severity of the symptoms, reduce the temperature, and decrease the liability to complications and sequels.

Beef Heart in Cardiac Disease.—Renon announces that he administers a powder from the ventricle of the ox heart, vacuum dried, dose 50 cgms. daily. He gives it for twenty days out of every month in cases of asystolia, especially of the left ventricle, with extrasystolic arrhythmia. Results are said to be good, but the author gives other cardiotonics as synergists.—*Le Bulletin Médical.*

Medicolegal Notes.

Evidence of Experiments as to Powder Marks from Pistol Shot.—On a trial for wife murder by shooting with a pistol the defense was that the deceased shot himself. The undisputed evidence was that there were no powder burns on the head or neck near where the bullet entered, and evidence of experiments made in regard to the effect of powder fired from the pistol which killed the deceased upon a napkin and upon tissue paper at distances ranging from three to ten feet was admitted to show the distance of the pistol from the deceased's head when the fatal shot was fired. On appeal from a conviction of manslaughter in the first degree the Oklahoma Criminal Court of Appeals holds that the trial court did not err in admitting evidence of the experiments as tending to shed some light on the firing of the fatal shot, and its weight was for the jury to determine. The court said: "As a general rule an experiment introduced for the purpose of proving that the alleged result is obtained by a certain act or operation, considered as existing in the case, should not be permitted unless the conditions and circumstances under which the experiment is made are similar to those shown actually to have existed in the case. However, if the evidence shows that the experiment was made under circumstances similar, or approximately similar, to those which surrounded the original transaction, it would be admissible, although such experiment might not have been made under exactly similar conditions as attended the original transaction. The want of exact similarity would not exclude, but would go to its weight with the jury."—Irby v. State (Okla.), 197 Pac. 526.

Demonstration by Physician as to How Deceased Could Have Been Shot with Pistol Permitted.—An appeal for a conviction of manslaughter, where the defense was that during a fight between the deceased and a brother of the accused the deceased was accidentally shot while the accused was endeavoring to disarm him, the defendant contended that the trial judge erred in refusing to require a doctor, under cross-examination, who testified to the bullet wounds in the body of deceased, to demonstrate by the use of a pistol, which figured in the homicide, how "the deceased could have been shot while holding the gun in certain positions." The Pennsylvania Supreme Court held that the regulation of cross-examination is always a matter of discretion for the trial judge, particularly how far actual physical demonstrations shall be allowed; and the court was not convinced of error in the trial court's ruling.—Commonwealth v. Barille (Pa.), 113 Atl. 663.

Proof of Accidental Means in Insurance Cases.—Where an insurance policy provides that the insurance is against "injury effected solely through external, violent and accidental means," the plaintiff must prove to a reasonable certainty that the death or injury was so caused. It is not sufficient to prove a declaration made by the deceased to his physician that his injury was so caused. There must be affirmative proof as to how the injury occurred, and the proof must show that it was accidental and caused through accidental means. The only testimony in an action on such a policy to establish the alleged accident was the statement by the deceased to his physician, who first treated an abrasion on his toe that he thought it was caused by his rubbing his toe with a towel. The physician had no knowledge of his own as to what caused the abrasion. When he was called to treat the abrasion he found the toe slightly infected. While the statement of the deceased to his physician was admissible to evidence for the purpose of showing the basis of an opinion by the physician, and his opinion as to the injury and the extent of the injury, it was held not sufficient to prove the main fact of the accident. As to this it was a mere self serving statement, and had no probative value as to such fact. It further appeared from his statement to his physician that, even if the injury had been caused by rubbing, the rubbing had been voluntarily done, and this would, therefore, not constitute an injury inflicted through accidental means. The proof was accordingly insufficient to establish any liability in the case.—United States Casualty Co. v. Malone, Mississippi Supreme Court, 87 So. 896.

MEDICAL RECORD.

PULMONARY TUBERCULOSIS IN CASES OF SURGICAL TUBERCULOUS LESIONS.

IN a very large majority of cases an attentive examination will reveal the presence of pulmonary lesions in different phases of evolution in cases of surgical tuberculosis, and statistics show that the lung process precedes the surgical lesions. But although pulmonary tuberculosis during lymphnode, bone, or joint tuberculous infection is often secondary, or at least presumed to be such, it may also be the first evidence of tuberculous infection, although it is impossible to determine the initial lesion in many instances. Between these two extremes should be placed those cases in which the lung was the first organ involved, and probably such are much more common than has generally been suspected. Therefore, the question should be studied under three heads, namely, (1) pulmonary infection in cases where the lesions have remained local for a long time; (2) bone, joint, and lymphnode infection in cases of pulmonary phthisis, and (3) the part played, probably important, by latent pulmonary or lymphnode infections giving rise to blood infection, in the genesis of surgical tuberculosis whose etiology is so frequently obscure.

It is generally stated in text-books that before making a prognosis of local tuberculous lesions the patient's general health and the presence of complications in other viscera—especially the lungs—should be first considered. Phthisis darkens the prognosis of white swellings, for according to Billroth, 16 per cent. of the subjects treated for this affection in his day died of pulmonary tuberculosis, while Koenig's later statistics are about the same. From the clinical viewpoint, two conditions are to be considered. The first embraces those cases in which a surgical tuberculous lesion follows a regular or even favorable evolution. Locally everything appears to be doing well, but a pulmonary lesion exists which kills the patient. In the second case the surgical lesion has caused much deformity, numerous sinuses, and marked enlargement of the lymphnodes, and tuberculous metastases occur in the lungs from the joint or bone lesion. Although tuberculous adenitis remains for a long time a local lesion the researches of Boulay and Heckel have shown that pulmonary tuberculosis often follows. Bone or joint tuberculosis seems to provoke pulmonary infection secondarily, while adenitis, especially in the neck, seems to be the normal course followed by the infection in reaching the lungs by lymphatic contiguity. According to Marfan, Boulay, and Heckel, the infection in the lymphnodes of the neck follows the cervicomediastinal lymphatic route and the lymphnodes of the mediastinum are most frequently involved when an infection of the cervical glands exists, at least this is what occurs in children and to some extent in adults. When, for example, the case is a joint tuberculosis an enlargement of the regional lymphnodes indicates that the bacilli have started on a general invasion of the body; they may reach the thoracic duct, and then the pulmonary circulation becomes arrested in the fine pulmonary capillaries. This mechanism is the same as that described by Calmette in the intestinal origin of tuberculosis of the lungs, and recent experimental work has shown the importance of the lymphatic system in the generalization of local tuberculous lesions.

When the tuberculous lesions of lymphnodes, bone, or joints are manifestly consecutive to pulmonary tuberculosis, the clinical picture changes. In these circumstances there is generalization of the infection; the bacilli invade the organism and create visceral lesions—bones and joints included—whose development is the result of frequent obscure factors. Trauma, however, seems to play an important part. Between primary and secondary osteoarticular manifestations there are often very marked clinical differences in respect to the aspect and evolution of the lesions. While in the former the lesions are circumscribed and slow in progress, in the latter the invasion is rapid. The invasion of the blood by leucocytes gorged with bacilli takes place either by the direct passage of the leucocytes through the pulmonary capillaries or from the presence of a tuberculous endarteritis of the pulmonary vessels. The great number of autopsies showing that pulmonary tuberculosis exists without giving rise to clinical manifestations is now a well known fact; a minute pulmonary lesion, susceptible of cicatrization may give rise to blood infection by one of the mechanisms referred to. Therefore the pulmonary lesions are often less evident than the osteoarticular processes and are apt to be overlooked. But there are cases in which the inverse is true, namely, that the lungs become secondarily infected from a tuberculous process in the bones or joints.

THE PROGNOSIS AND DIFFERENTIAL DIAGNOSIS OF ESSENTIAL FEVER IN GASTRIC CANCER.

THE prognosis of the febrile form of gastric cancer cannot as yet be definitely established on account of the relatively few reported cases; nevertheless,

it would appear from the case reports, and especially when the temperature assumes the intermittent type, that death occurs sooner than in cases of cancer of the stomach running the ordinary course. Generally speaking, when the elevation of temperature develops, a fatal outcome is not long delayed. The aggravation in the patient's general health following upon febrile paroxysms is readily comprehensible on account of the state of depression resulting therefrom, as well as the organic intoxication, the clinical manifestation of which is the febrile paroxysm. There are three affections that the febrile form of gastric cancer may simulate, namely, malaria, obscure suppurative processes, and pernicious anemia. When the gastric cancer is accompanied by an intermittent form of fever, two categories of cases are met with. In one, distinct signs of a gastric neoplasm are detected, or there are signs of probable cancer of the stomach; in the other, there are no digestive symptoms whatsoever. In the first category malaria coexisting with cancer or some internal suppurative focus must be eliminated from the diagnosis. In other circumstances the problem may be still more difficult, and before making a diagnosis of essential fever, a gastric neoplasm should be thought of and then the possibility of malaria must be considered. In all these cases the gastric manifestations are to be studied, an attempt being made to ascertain if they are simple painful paroxysms due to malarial infection or the result of a chronic affection of the stomach.

The type of temperature will not help in the diagnosis because in gastric cancer it presents the same character as that of malaria, while on the other hand larvate or abnormal forms of malaria give rise to peculiarities in the temperature making the diagnosis difficult. The most that can be said is that after paroxysms of essential intermittent fever an eruption of herpes or urticaria is never met with, although this is common in the malarial paroxysm. The patient's antecedents, the nature of his occupation, and the countries where he has lived are aids to the diagnosis of malaria, while an enlarged spleen also is important, but this enlargement is slight in recent cases and on the other hand the spleen may be increased in size in gastric cancer should it be the seat of metastases. The two important aids are the action of quinine and the blood examination. In the fever of gastric cancer quinine is ineffective. The presence of the malarial organism in the blood will settle the question of diagnosis but even when the results of the examination are negative malaria cannot be ruled out. Therefore several blood examinations should be made and the patient be under observation for some time.

The differential diagnosis from pernicious anemia is usually difficult, and in some reported cases of the febrile form of gastric cancer the former diagnosis was made. Several observers have endeavored to show that in cases of difficult diagnosis the hyperpyrexia taken by itself is an important element in the diagnosis, and affirms the existence of anemia. Consequently, this symptom has no value whatsoever since an elevation of temperature may also enter into the symptomatology of gastric cancer. Therefore, if the malignant gastric process assumes the character of pernicious anemia, the diagnosis will present great difficulty or may even become an impossibility. Gastric cancer, especially in the cases under consideration, may undergo a silent evolution, and since pernicious anemia is rare and cancer common, the gastric origin of the process should be carefully sought for by all our modern methods. Examination of the heart will indicate nothing because the presence of murmurs will be found in both morbid processes. In some cases indefinite diagnostic data may be obtained from analysis of the urine, but examination of the feces may be of real service in this respect. If the diagnosis of both gastric cancer and pernicious anemia can be eliminated, an attempt must be made, by a careful analysis of the patient's antecedents and the physical signs presented, to ascertain if the febrile manifestations are due to a suppurative process. Should this examination show that the accidents are due to gastric cancer one should try to discover if the fever is essential or symptomatic of a pus focus. In most cases this differential diagnosis cannot be made intra vitam except at operation.

PARATYPHOID FEVER SPREAD BY HEADCHEESE.

THE literature of detailed reports of clear-cut paratyphoid outbreaks in this country is very limited. This fact together with the unusual source to which the outbreak was traced makes the epidemic which occurred in Cascade County, Mont., in November and December, 1920, and recorded by Drs. Fred T. Ford and T. E. Walker in the *Public Health Reports*, xxxvi 35, Sept. 2, 1921, of unusual interest. On Nov. 27, 1920, there were reported to the Health Department of Cascade County thirty cases of influenza by the local physician, with the request that the county health officer come to Cascade for the purpose of seeing a number of the cases and instituting measures to prevent the further spread of the disease. The symptoms presented by these patients closely simulated the onset of influenza of rather severe type, but the blood serum of all but one of the twenty cases examined gave positive Widal reactions with *Bacillus paratyphosus* B, in a dilution of 1-40 in one hour. In no case was the reaction positive with *B. paratyphosus* A. In nine instances the Widal reaction was positive also with *B. typhosus*, this being undoubtedly by reason of group agglutinins.

With this finding an investigation was started to determine the source of the infection. The town of Cascade is a prosperous rural community of 430 inhabitants, nearly all of whom live in clean and well-kept homes. The water supply of the town derived from two sources was subjected to repeated

laboratory examinations, all of which failed to reveal the presence of *B. coli*. An epidemiological investigation was then carried out by means of a questionnaire answered by eighteen of the patients, through which it was found that in every instance the patients ill had eaten headcheese which had been purchased from a single meat market within the period November 17-20, inclusive. This headcheese was prepared by the proprietor of the market on November 17 and sold during the following three days. This was the only article of diet of a common source eaten by all the patients. The milk used was supplied by different dairies. There were no privately owned water supplies. Of thirty-four patients who had become ill up to and including November 30, twenty-eight had eaten the headcheese, and the other six, though denying that they had eaten of it, were members of families wherein the headcheese had been served and in which other cases existed. Several cases developed in two families living outside of Cascade. It was learned that the members of one these families had visited relatives in Cascade and eaten of the headcheese, while the other family had purchased some of the headcheese in Cascade, this being the only article of food purchased. Of the forty-four cases that developed in fifteen families throughout the course of the outbreak, from November 18 to December 18, thirty-seven were apparently primary cases. The seven secondary cases were easily accounted for as contact cases.

The question remaining to be answered was how the paratyphoid bacilli came to be in the headcheese. On carefully questioning the proprietor of the meat market, it was learned that his wife had been ill for a period of approximately four days three weeks before the outbreak. It was also learned that she had assisted in preparing the suspected food about two days before it was placed on sale. At the time of the investigation she was out of town so that it was impossible to obtain a Widal examination of her blood. In addition to the interest that attaches to a carefully investigated paratyphoid epidemic this study emphasizes the importance of investigations of supplies of food as well as of water and milk in connection with outbreaks of intestinal diseases.

THE RELATIONSHIP BETWEEN EPIDEMIC ENCEPHALITIS AND HERPES FEBRILIS.

THE knowledge of this association which is beginning to attract attention began in a way with the discovery by Grüter in 1913 that herpes of the cornea in man is transmissible to the rabbit. This line of research lay fallow for six years, and in the meantime epidemic encephalitis had appeared in Europe. The original experiments of Grüter were then repeated and extended, and it was learned that herpes of the cornea in rabbits may be propagated from animal to animal, and that inoculated animals developed immunity to further inoculation. Doerr and Schnabel of the Hygienic Institute at Basle, writing in the *Schweizerische medizinische Wochenschrift* for May 19, 1921, li. 20, state that Loewenstein apparently demonstrated also that in all cases of febrile herpes there is a common exciter. A new infectious disease had in other words been isolated and it presented apparently but a single lesion—herpes febrilis. The original conception was, however, greatly modified by Doerr and Vöchting, who showed that the herpes virus could produce a general disease-picture and even cause death. Some of the general symptoms were convulsions, paralysis, and salivation. Intensification of the virus and injection into the veins or subdurally showed that the nerve centers were vulnerable to its action. Finally it appeared that the induced rabbit disease had much in common with epidemic encephalitis when conveyed to the same kind of animals. It became evident that propagation from eye to eye of the herpes virus causes more than a local malady. In theory, material from an infected brain should be able to set up the corneal disease, though Doerr and Vöchting could not at first obtain this result. But if the brain emulsion was allowed to come in contact with a well scarified cornea by instilling a drop or two into the corneal sac, positive results were obtained which closed the chain of proof. Hence herpes virus can apparently not only cause a purely local affection—albeit one attended by fever—but it can also by mere inoculation of the cornea show a pathogenic neurotropism, causing infection of the central nervous system.

A later find was a metastatic keratitis present in cases of general infection. This explains the tropism of the exciter of the disease toward the cornea, which at the same time becomes immune to further attack. The author later was able to show that the other cornea shared in this immunity and that immunity in the inoculated cornea was merely a phase of total acquired immunity. We have here then a disease which shares features with a group of infections of the central nervous system, including rabies, poliomyelitis, and epidemic encephalitis. In the case of the latter malady the question of identity has come up. A comparison is restricted thus far to laboratory diseases. Encephalitis virus inoculated into the rabbit cornea can set up a local infection, although the author does not term it a herpes, nor does he state the contrary. In the laboratory encephalitis of rabbits the animals were refractory to inoculation of the cornea with herpes virus. In general the experiments showed the existence of double or crossed immunity. This points to identity of virus, although no exciter has ever been isolated in either disease. Clinically to claim any identity between so banal and innocent a condition as herpes febrilis and a malady like epidemic encephalitis would, to say the least, be premature. Moreover, it has not yet been possible to cause corneal herpes in rabbits by inoculation with the infected brain tissue of human encephalitis or with lumbar punctate from the living victim of the latter. The question of separate strains of a com-

mon disease exciter must necessarily come up and there must be further experiment before the question of identity can be settled.

Arsphenamine vs. Novarsphenamine.

In France, at least, novarsphenamine, or novarsenobenzol as it is there called, has been generally accepted by the medical profession, probably because of its very easy preparation for immediate use. Nevertheless, some syphilologists remain faithful to 606. Of this number belongs Queyrat, who has very recently given his reasons for this preference. This observer, with his collaborator Millet, has for one year treated comparatively similar cases with each of these arsenical products in equivalent doses, namely, three grams of arsphenamine and four grams of novarsphenamine. They found that after the end of the treatment the Bordet-Wassermann reaction was less often negative in the subjects treated with novarsenobenzol than those treated with arsenobenzol. The proportion was 25 per cent. more positive reactions in the primary stage and 28 per cent. in the secondary stage. Besides, a negative reaction appears to be less durable after treatment with novarsenobenzol, while relapses and secondary accidents are much more frequent. On the other hand, Queyrat believes that novarsphenamine is much more prone to give rise to hepatic complications, which may be serious in a few cases, made manifest by malaise, elimination of urobilin, fever, erythemata, and a large, tender liver. The milder complications are reduced to icterus, which is exceptionally met with when arsphenamine is given. If in spite of these drawbacks neosalvarsan is used, Queyrat then maintains that the product should be injected in very dilute solutions in the proportion of one part of the drug to five parts of serum. As a last argument in favor of arsenobenzol, these observers find it advantageous that when the needle does not enter the vein there is pain from the injection in the subcutaneous tissues. Thus the physician being immediately warned that the needle is not in the lumen of the vessel, the injection can be made at another spot, while with novarsenobenzol there is risk of local complications which may last for some time, because one is less quickly warned when this product is injected outside a vein.

Familial Incidence of Quinsy.

Leegaard has for years investigated the subject of the possible familial incidence of phlegmonous angina, and always, when encountering a new case, he notes whether any other immediate relatives are subject to the same ailment, and has found positive results quite frequently. (*Norsk Magazin for Laegevidenskaben*, May, 1921, lxxxii, 5.) The number of primary cases seen was 120, of which 52 were in male and 68 in female subjects. The maximum incidence was during the age period, 20-25, and the great majority of all cases occurred between the ages of 15 and 35. Of the 120 patients 44 had no immediate relatives with history of quinsy, while 43 had one relative thus affected, 13 had 2, 8 had 3, 5 had 4, and 5 five relatives with the same ailment. Finally there were two patients who each had no less than eight near relatives with history of quinsy. In other words, 76 out of 120 patients had near relatives who suffered from this affection. The total number of these second cases adds up to 170, although the author for some reason makes this total only 154. The relationship comprised parent, grandparent, brother or sister, uncle or aunt, nephew or niece. It now became necessary to take controls who had never themselves had quinsy, and of 110 such patients but 10 had relatives who had suffered with the disease. The familial character of quinsy is thus rendered possible or even probable; but it must be noted that a person who had never himself had quinsy would be less likely to hear of or to remember similar cases occurring in relatives living apart from him, possibly in another city. Of further interest is the number of attacks of quinsy in the 120 patients. In 23 there had been but one attack, in 17 but two attacks, while in 73 the attacks had occurred so frequently that the author terms them habitual. It is the patient with habitual quinsy who shows much the greatest tendency to familial incidence, as shown by supplementary figures of the author.

Provoked Inequality of the Pupil in the Diagnosis of Early Tuberculosis.

Professor Sergent, who has long made a study of the precocious diagnosis of pulmonary tuberculosis, last April announced the discovery of a possible new sign (*Journal de médecine et de chirurgie pratiques*, June 10, cviii, 11). He terms this "provoked mydriasis." Before that period he had traced a connection between pupillary inequality and the presence of a dry apex pleurisy in which the sympathetic nerve was the transmitting agency. Apparently filaments of these nerves are involved in certain enlargements of regional lymphnodes. In certain cases subsequent miosis was explained by destruction of the said fibers. As a spontaneous phenomenon not much could be expected of it in diagnosis and therefore Sergent tested suspicious cases with mydriatics in both eyes. The latent period is counted as 10 minutes and dilatation reaches its maximum in 25. Upon the theory that the aforesaid lesions will sensibilize the sympathetic on the diseased side the author expected a precocious reaction. Ten normal subjects tested were found to present bilaterial symmetry in mydriasis. Of 18 subjects known to have unilateral apical trouble 11 showed inequality. In another series of 22 suspicious cases 15 gave a positive result. In addition to the frankly negative results there were a number more or less anomalous and it would seem that the stage of the lesion and resulting cicatricial changes play a role.

News of the Week.

Typhoid Spreads in New Jersey.—Following the recent epidemic of typhoid fever in Burlington County, five cases of this malady have developed in Hamilton Township, Mercer County. Twelve other persons are ill and it is feared that they also have

the disease. The State Board of Health is conducting an investigation and believes the milk supply is responsible.

New York Scores Lowest Death Rate.—The mortality record for the week ending September 23 is the lowest ever experienced by the city of New York, there having been only 967 deaths recorded with a death rate of 8.77 per 1,000 of the population. Other low death rates are those of July 17, 1920, of 9.00; September 20, 1919, 9.04; August 31, 1918, 10.05, and June 14, 1917, 10.95.

Infantile Paralysis Cases Increase.—The number of cases of poliomyelitis reported to the New York City Department of Health for the week ending September 24 was the largest recorded in any single week since the epidemic of 1916. There were 69 cases reported, and of these 19 were discovered as the result of a canvass of 7000 homes by the nurses of the department. Health Commissioner Dr. Royal S. Copeland has emphasized the importance of excluding from the schools any child presenting symptoms of catarrhal fever or suspicious evidence of acute disease, and has published instructions in the lay press aiming at the prevention of contact infections.

Physicians Must Be Morally Fit.—A decision recently handed down by Chief Justice Rugg in the Supreme Court of Massachusetts, declares that soundness of moral fiber to insure the proper use of medical learning is as essential to the public health as medical learning itself. "Mere intellectual power and scientific achievement without uprightness of character may be more harmful than ignorance," the court asserted in overruling exceptions of a practising physician of Boston, who had been requested to appear before the State Board of Registration in Medicine and show cause why his certificate should not be revoked for alleged gross misconduct in his practice. "Highly trained intelligence combined with disregard for the fundamental virtues is a menace," Justice Rugg said. "A physician, however skilful, who is guilty of deceit, malpractice, or gross misconduct in the practice of his profession, even though not amounting to an offense against the criminal laws, well may be thought to be pernicious in relation to the health of the community. The circumstances that the petitioner already had been registered and given a certificate to practise medicine gave him no immunity against future legislation."

State Society Initiates New Activity.—The Ohio State Medical Association has started a series of group meetings for postgraduate clinical study throughout the State this fall. Some eighteen or twenty locations have been selected where these meetings will be held, to which physicians from all surrounding counties are being invited.

Hospital Notes.—A site has been purchased for a general hospital in North Baltimore and construction operations will soon be undertaken. This will be the first hospital in North Baltimore. It will be managed by Dr. G. W. Foltz and Dr. Earl Foltz.

Improvements, which it is estimated will cost $300,000, are being made at the State Hospital for the Insane at Farnhurst, Delaware. When completed this institution will have an equipment modern in every respect.

Structural alterations in the buildings of the Hospital of the Rockefeller Institute have been completed and the hospital reopened for the admission of patients on September 19. The hospital confines its work to selected cases that bear upon a limited number of subjects chosen for investigation. The conditions that will be the subject of special study during the coming winter are nephritis, cardiac disease, acute rheumatic fever, acute lobar pneumonia and other acute pulmonary infections. Patients suffering from these diseases will be admitted to the extent of the hospital facilities. Physicians wishing to have patients admitted may communicate with the hospital by telephone or by personal application to the Resident Physician.

The new annex to Grady Hospital, Atlanta, Ga., was opened on September 18. It provides two hundred additional beds.

Examination of Food-Handlers in New York City.—During the past year a total of 17,143 food-handlers and industrial workers were examined in the occupational clinics conducted by the Bureau of Preventable Diseases of the Department of Health. During the same period 55,673 examinations of food-handlers were made by private physicians. A comparison of the results indicates that the private physicians are not all contributing conscientiously to the protection of the public health from the food-handlers who may be affected with communicable disease. Excluding the industrial workers, 16,484 food-handlers were examined in the Occupational Clinics of the city, 28 per cent. of whom were found to present a physical defect of significant character. A ratio of 278 per 10,000 food-handlers was found to have sputum positive for the tubercle bacillus. If this same ratio obtained among all food-handlers in the city, there would be 19,275 such food-handlers in the City of New York. In the city as a whole 104 cases of active syphilis were excluded, giving a ratio of 65 per 10,000 food-handlers. Since examinations are made only once a year it is possible that many infections may occur in the interval between examinations. If the ratio found in this series prevailed among the three-quarter million food-handlers in the city, there would be a total of 10,350 cases of syphilis among this vocational group. There were 28 male food-handlers in whom evidence of chronic gonorrhea was found. If this ratio is assumed to represent the prevalence of this infection among food-handlers we may expect to find 4,350 such cases among the food-handlers of the city. A total of three active, chronic typhoid carriers were discovered by the clinic staff. In addition there were a number of parasitic skin affections, and one case each of diphtheria and of scarlet fever.

The Second International Congress of Eugenics was held at the American Museum of Natural History, New York, September 22-28, 1921, under the presidency of Professor Henry Fairfield Osborn. Among foreign representatives attending the meetings were: Dr. A. Govaertz, Belgium; Dr. D. F. Ramos, Cuba; Senor Dr. Don Arturo Scroggie, Chile; Dr. B. Feierabend and Dr. A. Sum, Czecho-Slovakia; Mr. Georg Bach, Denmark; Major Leonard Darwin and A. Barbara Dale, England; Mr. Manuel Dieguez, Guatemala; Messrs. Lucien Cuenot, Lucien March and George Vacher de Loupougue,

France; Mr. Sane Naccarati, Italy; Dr. Jon. Alfred Mjoen, Norway; Dr. Ales Hrdlioka, Prague; Dr. A. F. Tredgold, Edinburgh, Scotland; Dr. Phya, Medha, Siam; Dr. J. Varela, Uruguay; Mr. E. Arroyo Lameda, Dr. N. D. Dakin and Dr. R. Ruggles Gates, Venezuela, and many others. In addition to the scientific meetings a number of excursions about New York were arranged for the guests, among them one to the Eugenic Records Office of the Carnegie Institution of Washington at Cold Springs Harbor, L. I., and one to the country home of Dr. Henry Fairfield Osborn at Garrison, N. Y. The keynote of the various papers presented seemed to be in agreement in emphasizing the importance of heredity. While it was admitted that training and environment have an influence, the chief factor which determines the extent of an individual's mental development is his inborn potentiality for such development. As Professor Osborn put it, "There is no form of matter so stable as the germ plasm on which heredity depends." From the practical standpoint he finds little promise from the "melting pot" theory. All experiments have shown quite definitely that the mixture of a poor stock with a good one does as much harm to the good stock as it does benefit to the poor. From the practical standpoint the eugenists see little of promise for America in an unrestricted immigration. It is confessed that as yet the eugenic program has not proved eminently practical. The sterilization of the obviously unfit is legalized in a dozen States, but is practised in very few. The idea of a standard of physical health for marriage has encountered obstacles of prejudice, and indeed of practicability, which are apparently insuperable. The hopeful factor in the situation is that progress, however slow and halting, can already be discerned both in the public conscience as to marriage and in the collection and interpretation of scientific data.

American Medical Association Reestablished in Vienna.—This organization which, prior to the war was of excellent service to all English-speaking students in the city was dissolved at the outbreak of the war. It has now been recalled into existence. Some of the old functionaries have again taken up their offices, and in a short time the old conditions will be found again.

The New York Electrotherapeutic Society will hold its next meeting at the United States Naval Hospital in Brooklyn on Wednesday, October 5, 1921, 8.30 P. M. The program will include exhibition of equipment, methods and results of treatment, and moving pictures. All physicians are invited. Dr. Victor Pedersen is president of the society.

Dr. John G. Heisler has been elected Professor of Anatomy in the University of Pennsylvania in succession to Dr. George A. Piersol recently resigned.

Dr. W. Estelle Lee has been appointed by the Governor a member of the Pennsylvania State Board for Medical Education and Licensure in succession to Dr. John M. Baldy, and Dr. W. M. Hillegas has been reappointed to the Board.

Increased Dental Facilities for School Children.—The Bureau of Child Hygiene of the New York City Department of Health, with funds appropriated for increasing its dental service, which became available on September 1, has appointed four dentists, six dental hygienists, and eight nurses. The Bureau was given sufficient appropriation to appoint five dentists on full time as against nine on half time, eighteen hygienists, and nine new nurses. It is planned to operate eight new clinics apportioned among the various boroughs, one being established in Richmond, which, to date, has had no departmental dental service.

Infant Mortality in New York City.—The records of the New York City Health Department show that for the first thirty-five weeks of the year, ending August 27, the infant mortality rate was 76 per thousand children born, as against 91 for the corresponding period of last year. In 1885, the infant mortality rate of the city was 273.6 per thousand children born.

Health Exposition.—A public health exposition will be held at the Grand Central Palace on November 14, under the joint auspices of the New York City Health Department and the American Public Health Association. The proceeds from the sale of tickets will be used to aid in financing the annual convention of the American Public Health Association and to establish nutritional clinics in New York City for the benefit of undernourished children.

Position for Scientific Aid.—A vacancy in the Division of Physical Anthropology, National Museum, Washington, D. C., at $125 a month, is announced by the United States Civil Service Commission. A competitive examination will be held on October 19, 1921, from which this vacancy and others requiring similar qualifications will be filled. Applicants must have completed three years of college or university work (preferably in a medical school), or have had at least one year's experience in a laboratory of physical anthropology. Applicants should apply at once for Form 1312, stating the title of the examinations desired, to the Civil Service Commission, Washington, D. C.

Vacancies in Civil Service Positions.—The New York State Civil Service Commission announces an unwritten examination for First Assistant Superintendent (physician), to fill a vacancy at the New York State Reformatory for Women at Bedford Hills. The salary is $3,000 and maintenance. Candidates will be rated on training, experience and personal qualifications. The age limits are 25 to 50 years. Candidates must be graduates of an incorporated medical school and have had at least three years in medical work since graduation.

An examination is also announced to fill the position of Assistant Bacteriologist, State Department of Health. The salary is $2,250. The age limits are 25 to 45 years. Candidates must have had a college education or equivalent training in chemistry, physics and bacteriology and four years practical experience in the bacteriological and serological diagnosis of infectious diseases. This position is open to non-residents and non-citizens. Application forms for unwritten examinations may not be sent out after October 20 and for the written examinations not after October 10. Application for forms should be made to the Civil Service Commission, Albany, N. Y.

Charitable Bequests.—By the will of the late Mary Powers Harris, of Philadelphia, bequests are made as follows: Children's Hospital, $25,000, for

the erection of a separate building or wing for the treatment of crippled children, to be known as the Thomas H. Powers Memorial; Pennsylvania Hospital, $8,000, for the endowment of a free bed; Home for Incurables, $8,000, for the endowment of a room; Home of the Merciful Saviour for Crippled Children, $5,000; Chestnut Hill Hospital, $5,000, as a memorial to Anna M. Powers; Orthopedic Hospital and Infirmary for Nervous Diseases, $5,000.

Medical Society Elections.—The Wisconsin State Medical Society, at its annual meeting in Milwaukee, September 8, 1921, elected the following officers for the ensuing year: *President*, Dr. Sidney S. Hall, Ripon; *first vice-president*, Dr. Louis M. Warfield, Milwaukee; *second vice-president*, Dr. Spencer Beebe, Sparta; *third vice-president*, Dr. Rolla Cairns, Rivers Falls; *secretary-treasurer*, Dr. Rock Sleyster, Wauwatosa.

The Tenth Councilor District of the Arkansas Medical Society at its annual session at Fort Smith, September 8, 1921, elected the following officers for the ensuing year: *President*, Dr. William R. Reeves, Alma; *vice-president*, Dr. J. G. Eberle, Fort Smith; *secretary-treasurer*, Dr. J. G. Wolfermah, Fort Smith.

The Union County (N. J.) Professional Guild, organized on September 8, with a membership of three hundred physicians, dentists, druggists and nurses, elected the following officers for the ensuing year: *President*, Dr. Norton L. Wilson, Elizabeth; *vice-president*, Dr. Charles L. Hardy (dentist), Summit; *Secretary*, Miss M. E. Kernan (nurse); *treasurer*, Louis Langman (druggist), Elizabeth.

The Cumberland Valley Medical Association, at its annual meeting held in Hagerstown, September 12, 1921, elected the following officers for the ensuing year: *President*, Dr. W. D. Campbell, Hagerstown; *vice-presidents*, Dr. W. A. Gordon, Hagerstown; Dr. LeRoy H. Sape, Fannettsburg, Dr. S. Dana Sutleff, Shippensburg; *secretary*, Dr. John H. Coffman, Scotland; *assistant secretaries*, Dr. Warren D. Miller, Hagerstown; Dr. Frank N. Emmert, Chambersburg; Dr. C. R. Rickenbaugh, Carlisle; *treasurer*, Dr. John C. Gilland, Greencastle.

The Wisconsin Association of Industrial Physicians, at its annual meeting held in Milwaukee, September 9, 1921, elected the following officers for the ensuing year: *President*, Dr. C. F. Schram, Beloit, *vice-president*, Dr. R. A. Waite, Milwaukee; *secretary-treasurer*, Dr. R. E. Fitzgerald, Milwaukee.

Obituary Notes.—Dr. W. B. Cory, general medical examiner of the Brotherhood of Locomotive Firemen, died suddenly of heart disease at his home in Cleveland, Ohio, on September 23, at the age of forty-four years. He was graduated from the University of Illinois College of Medicine in 1901.

Dr. Wilfred B. Cunningham of Mamaroneck, N. Y., a graduate of Harvard Medical School in 1903, died on September 12, at the age of forty-two years.

Dr. Edward Rawson of Battle Creek, Mich., died in a local hospital on August 30, at the age of eighty-four years.

Dr. Clarence Jaquins Wallace of Wilkesbarre, Pa., a graduate of Hahnemann Medical College, Philadelphia, in 1889, died on August 29, at the age of fifty-four years.

Dr. Joseph H. Peck, a retired physician of Cleveland, Ohio, died at his winter home in Fort Orange, Fla., on August 30, at the age of eighty years. He was graduated from the Western Reserve University School of Medicine in 1883.

Dr. Charles W. Ray of Waxahachie, Tex., a graduate of Vanderbilt University Medical Department, Nashville, Tenn., in 1916, died suddenly on September 6, at the age of thirty-five years.

Dr. John M. Pleasants, former Mayor of Petersburg, Va., died September 1, at the age of eighty-eight years. He was graduated from the Baltimore College of Medicine in 1852, served as state senator, and was for a time editor of the *Index-Appeal*.

Dr. Margaret E. Holland of Houston, Tex., a graduate of the Northwestern University Woman's Medical School in 1873, died on August 31, at the age of seventy-three years.

Dr. William L. Fitts of Atlanta, Ga., a graduate of the Emery University School of Medicine, Atlanta, in 1883, died on September 8, at the age of fifty-nine years.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, Sept. 6, 1921.

Post-Graduate Training in London.—The Bulletin of the Fellowship of Medicine and Post-Graduate Medical Association in its issue of September 3, last, discusses the future of post-graduate medical education in London. It is pointed out that it may be that, as the years pass, it will acquire the position of a specialism requiring an expert in the subject to organize and regulate the courses. Should this eventually materialize each scheme of the kind would demand the appointment of a "Director of Studies," in some respects resembling the position of that of a dean in a medical school. The director's duties, however, would be different from those of a dean: they would be of a more responsible nature, for while in the case of the latter the medical student's education is regulated by the demands of the curriculum, the instruction of the post-graduate has to conform to the special requirements of those by whom the instruction is sought. These requirements, of course, vary according to the position of the post-graduate. He may be a general practitioner, seeking to add to his knowledge in general medicine and surgery. For him the ordinary courses in both of these subjects would probably suffice. In his case the director's advice would present no difficulty. But something more in the way of advice would be necessary where the post-graduate applied for instruction, say, in one of the special departments. Here the director would be enabled to discharge the duties of his position with material benefit to the post-graduate. Let it be supposed that the latter presents his requirements in the following form: "I want to study diseases of the nose, throat, and ear. Can you put me in the way of making the best use of my time?" Under these circumstances the director, fortified with the full knowledge of the necessary procedure, would be able to draw up a schedule, including the hospitals to visit,

the lectures to attend, the special features of the courses provided to which attention should be given and other details of importance. In short, a "plan of campaign" would be devised and presented to the post-graduate which would soon prove to be to his advantage to follow. The same also would apply to every other special department. The fact is emphasized that one of the chief and most pressing difficulties encountered by a foreign post-graduate visiting London for the first time is to learn the geography of this great metropolis. The director could render him help in this direction. Merely to be told that certain hospitals must be visited leaves the post-graduate parlously placed for ascertaining for himself the precise locality of the institutions and the best means of visiting them. A few hints upon this point when desired could not fail to be appreciated where all was strange, novel, and difficult in regard to the environment. In order that full use should be made of the "director's" position, notification would be required to be given that post-graduates should consult him in all cases respecting their requirements.

It may be added that the report of the secretary to the Fellowship of Medicine Post-Graduate Association is most satisfactory in respect to the number of post-graduates joining the association during the present vacation season. Some of these have come from far distant parts of the Empire. In two or three instances Vienna has been the main objective of the visit to Europe. But having become acquainted, on arrival in London, with the facilities offered by the association, the post-graduates have decided to delay their journey to Austria, and have taken out a modified course in London. As has been said many times in these letters, London presents advantages for post-graduate medical training possessed by, perhaps, no European city. Its clinical material is unrivaled and to Americans the fact that it has a common language is no mean point in its favor. The drawbacks are that there is a lack of organization and that the financial situation is not satisfactory. If the medical profession of London would grapple with the problem with the enthusiasm and zeal its importance deserves, there is little doubt that London would soon take its rightful place as the first post-graduate center of Europe, at any rate, for English-speaking post-graduates.

Address of Sir James Crichton Browne at the English Conference of the Sanitary Inspectors' Association.—The thirty-fourth annual conference of the Sanitary Inspectors' Association, which commenced at Bath on August 31, was rendered notable by a stirring valedictory address by Sir James Crichton Browne, who resigned the position of president after a tenure of twenty years. Sir James's address was largely taken up with the growing social evil. He said that the subject was of such a character that one would rather not refer to it in a public assembly, but knowing what he did of the horrors of the disease it would be culpable prudery if he refrained, at such a meeting, from indicating what he believed was the one sure way, and that was not a clinic, of coping with a grave and growing social evil. He pointed out that during the past year 2,023 deaths in England and Wales were due to syphilis, and 2,103 to other venereal diseases. These figures, however, afforded not the slightest conception of the havoc wrought by these maladies. Not less than 10 per cent. of the population of the large English towns were infected with syphilis, and a much larger proportion with gonorrhea. Gonorrhea was prolific of sterility, blindness, and of rheumatic and joint affections, and syphilis was the direct cause of a vast number of cases of abortion, miscarriage, stillbirth, and infant mortality and as a hidden assassin, was undoubtedly responsible for a large number of deaths attributed to other causes, such as aneurysm, angina pectoris, Bright's disease, and cerebral hemorrhage. Syphilis was the sole cause of general paralysis of the insane, which killed 2,000 people in Great Britain annually, and it was the inexorable bane of those men they saw staggering about with locomotor ataxia.

The speaker went on to say that the disease could be prevented, and if he were asked why it was not prevented, the answer must be because of ignorance and negligence on the one hand, and ecclesiastical prejudice and short-sighted morality on the other. All were agreed that the proper and infallible preventive against venereal disease was chastity and marital fidelity; but these had failed and failed lamentably; our troubles had accumulated, and we had now within our reach a physical preventive which must not be ignored until moral preventives had been reinforced and proved effectual. There was the clearest and most definite medical evidence that the spread of venereal disease could be prevented by the adoption of methods of self-disinfection. The first suggestion of this was met with shouts of protest. It was pronounced a premium on vice and an encouragement to promiscuous sexual intercourse by removing the risks attending it. He then proceeded to criticize severely the policy of those who held views antagonistic to those of the Society for the Prevention of Venereal Disease. The speaker laid stress on the point that the deterrent effect of venereal disease was greatly exaggerated. If it was an effectual deterrent, why was the disease so disastrously prevalent? In any campaign against venereal disease many measures were necessary. There must be the suppression of unqualified quacks and herbalists, who had done so much mischief and the prohibition of their alluring advertisements. There must be established a network of clinics and hospitals throughout the country in which treatment by the most modern and approved methods could be carried on, and hostels for the prolonged treatment of women and girls. There must be laboratories in which pathological investigation and diagnostic work could be carried out. Contacts must be supervised and all disclosed cases followed up. But, above all, the public must be educated as to the incidence and dangers of venereal disease and as to preventive measures, among which immediate personal disinfection must take the first place. He was convinced that that was the best weapon for combating venereal disease.

The Study of Pathology.—Pathology is a subject which cannot be studied too closely by the medical student, or, perhaps, more especially by the post-graduate medical student. The correct diagnosis of disease is absolutely essential if the treatment is to be successful, and the foundation of an ability to detect the origin of disease with even fair accuracy is laid by the intelligent comprehension of good text-books, although, of course, the coping stone of this knowledge is only placed by clinical experience and by the opportunity of making post-mortem examinations. In the presidential address at the recent meeting of the British Medical Association at Newcastle, given by Dr. David Drummond, particular emphasis was put upon the need for facilities for more post-mortem examinations. This need is obvious and so is that for reliable text-books of general pathology.

Obituary.—Dr. Herbert Edmund Cuff was drowned at Burnham Overy on the Norfolk coast on August 15, last, in an effort to save his two daughters, aged 15 and 12, respectively, who were bathing and got into difficulties. Doctor Cuff's wife witnessed the tragedy from the shore. The endeavor to save the children was unavailing, and she saw her husband and her only two children go down before her eyes. Doctor Cuff was principal medical officer to the Metropolitan Asylums' Board. He was an exceptionally able man, endowed with the tact and common sense essential to one in control of an immense staff as that of the Metropolitan Asylums' Board. He was beloved and respected by all his colleagues, and his tragic end came as a severe shock to all who knew him.

2. Cancer.—John E. Talbot offers a line of thought which gives a new conception of the process involved in the production of cancer. He points out that there are at least three well known and established syndromes which result in cancer. First, the race that eats very hot rice suffers from cancer of the esophagus, which affects only the men and not the women. This is undoubtedly due to the fact that the men eat at the first table, so to speak, and thus get the rice at its hottest. Second, another race whose custom it is to wear a charcoal stove against their abdomen suffers from cancer of the abdominal wall, which is almost unheard of elsewhere. Third, among our own race there is an association between cancer of the lip and the frequency of smoking a clay pipe. These three well known clinical entities have given basis for the belief that cancer is in some way due to chronic irritation. In each of these forms of irritation there occurs a death of surface epithelium which is a normal process and calls for replacement of the germ cells of the skin. There are two extraneous influences acting, an abnormal temperature and a call for a great increase in rapidity of replacement. This process stimulates the germ cells of the affected tissue to activity greater than is physiological. The process not only calls for rapid reproduction of physiological cells, but also stimulates *an increased reproduction of germ cells* themselves. In order to keep this rapid reproduction process in physiological control, each new germ cell must acquire a trophic nerve attachment. Failing in this we have a germ cell containing the inherent power of reproduction, provided it has sufficient food supply and is kept at the proper temperature. Unless this nerveless cell is controlled by acquiring its trophic nerve connection, we have the exact situation present in cancer of rapid cell reproduction without physiological trophic nerve control. This point of view places bacteria and the dissociated cell of the complex organism on a like basis. The great difference between these single cells, the bacteria and the dissociated tissue cells in their action on the complex organism lies in the fact that the bacterial cell is a foreign invader to which the complex organism has developed a partial or complete defense or immunity. The by-products of the dissociated cells, however, are of the same nature as the by-products of the other similar tissues of the body, and the complex organism is, therefore, unaware, so to speak, of the local process until it overwhelms the life processes of the complex organism. It is suggested that the mechanism for maintaining the interrelationship of tissue growth is the sympathetic nerve system, more specifically spoken of as the trophic nerves.

3. The Etiology of Hysteria.—Max Baff states that the study of a large number of cases of hysteria shows that, although profound emotional shock is the cause of onset of an hysterical convulsion, it is not the cause of hysteria itself. Hysteria is not caused by intense worry or by concentration of the mind upon itself. The emotional shock simply acts as a cause for the patient to lose her conscious mind, and thus be thrown into a subconscious mind, or the "unconscious." Hysteria is not hereditary. Perhaps it runs in families because parents give to their children the same treatment during life which they themselves received when children. That which is hereditary is the baby constitution, the infantile and undeveloped self-control. As children the hysterics have always had their own way, and the practice of giving to children anything they desire is full of folly and independence is sadly lacking in them during their future years. When an individual of this type is confronted by misfortune, instead of fighting it, she goes into an hysterical attack, thus substituting for her conscious mind her unconscious mind, which brings her back to the days of her childhood when all was serene. Psychoanalysis, coupled with a study of the manner in which the patient goes through her emotional demeanor, will discover to her her weaknesses and her failures which gave her a diminution of self-control.

3. The Toxin Treatment of Dermatitis Venenata.—Albert Strickler has investigated the following problems: (1) What curative influence does the toxin of *Rhus toxicodendron* possess on the symptoms and course of dermatitis venenata due to poison ivy or oak? (2) Is it possible to desensitize individuals against dermatitis venenata produced by poison ivy, oak, or sumac? (3) What is the probable duration, and what constitutes the best method of desensitization? As a result

of his experience with thirty cases, and also that of Alderson and Petch, he concludes that: (1) The intramuscular injection of the toxin of *Rhus toxicodendron* or the toxin of *Rhus venenata* can cure the dermatitis produced by poison ivy, oak, or sumac. (2) As a rule, the subjective symptoms associated with this affection disappear or are greatly modified within twenty-four hours after the first injection is given. (3) No more than four injections are necessary to produce a cure, two injections are usually sufficient. (4) The injections are given intramuscularly at twenty-four-hour intervals. The dose of the diluted toxins varies from 0.5 c.c up to 1 c.c., although as high as 2 c.c. can be given. (5) The result in the writer's series of cases was secured without the use of any local applications whatsoever. (6) It appears highly probable, in view of the results obtained by various observers, that it is possible to establish a desensitization to ivy poison and oak poison. The desensitization is probably temporary in character, and one that has to be renewed from time to time. (7) The intramuscular injections combined with administration by mouth offer the most logical procedure, and the one best calculated for obtaining a most satisfactory result.

6. The Clinical Diagnosis of Heredosyphilis.—Henry Stoll. (See MEDICAL RECORD, July 2, c, 1, p. 39.)

7. Granuloma Inguinale (Granuloma Venereum; Granuloma of Pudenda; Ulcerative Vulvitis; Serpiginous Ulceration of the Genitals, Etc.).—Kenneth M. Lynch finds that in his community as well as probably throughout the South, if not throughout the nation, a fairly prevalent condition has been passing under the general class of venereal sores and has not been recognized as it has been in other parts of the world (notably in warmer countries) as an entity. He concludes that there is a type of pure case, but there are also cases in which the condition is similar, if not identical, and Donovan's organism present, but which appear to be secondary to or at least associated with other conditions. In all the cases reported the Donovan organism was obtained in smears, the more acute and progressive the lesion the larger numbers present. In the treatment of these cases U. S. P. commercial tartar emetic in a 1 per cent. solution in physiologic sodium chloride solution or distilled water, and sterilized by filtration, was employed. The usual procedure was to start with 3 c.c. of the 1 per cent. solution diluted to 10 c.c. with either sterile physiologic sodium chloride solution or distilled water, increasing the dose 2 c.c. every third day until 12 c.c. of the undiluted 1 per cent. solution was reached. In granuloma plus syphilis tartar emetic is used between the injections of arsphenamin. When it was possible to do so the lesion was completely excised and healing supported by tartar emetic injections. In the pure condition healing has resulted in fairly extensive lesions within four or five weeks, and even in the most extensive persistence in treatment will effect results in time.

10. Studies on Aneurysm.—Baldwin Lucke and Marion Hague Rea report general statistical data on aneurysm obtained in an analysis of 321 aneurysms of the heart and its valves, the aorta and the aortic branches. In 12.000 post-mortem examinations at the Philadelphia General Hospital and the Hospital of the University of Pennsylvania, 321 "intracorporeal" aneurysms occurred in 268 or 2 2 per cent. of the patients examined post-mortem. The main facts brought out are that aneurysms are more frequent in the United States and Great Britain than in the Teutonic countries. This may be accounted for by the existence of different spirochetal strains possessing selective affinities and being particularly prevalent in certain countries or races, or by a predisposing influence on the vascular structures of racial characteristics. The aorta is more often involved; the various aortic branches are relatively rarely the seat of aneurysms. The most frequent age period for aortic aneurysm is the fourth and fifth decades. Aneurysm occurs at an earlier age in the negro than in the Caucasian race. Aneurysm occurs about four times more frequently in males than in females. Practically all writers are in accord on this point. Aneurysm is relatively more common in the negro than in the Caucasian. In fifty-three patients, 20 per cent., in this series multiple aneurysms were found. It is not uncommon to find one aneurysm diagnosed yet two or three are discovered at autopsy. The clinical diagnosis was made in 43 per cent. of these cases. Aneurysms frequently escape clinical detection. The conditions most frequently mistaken for aneurysm are asthma, chronic endocarditis, chronic myocarditis, pulmonary tuberculosis, and mediastinal tumor.

11. Coccidiosis in Man as a Possible Sanitary Problem in the United States.—Frank G. Haughwout recalls that in 1918 he called attention to the growing number of cases of human coccidiosis that were being reported from the war zones abroad, and ventured the opinion that war conditions were not unlikely to bring about a spread of the parasites involved. He now claims that the prediction is on a fair way to be fulfilled, and points to the records of eleven cases of coccidiosis discovered in the United States since he wrote the paper. To these he adds another case. Of the cases reported seven occurred in men who had been in service overseas, and four in home service troops. He thinks it desirable to follow the peregrinations of these infected soldiers and to inquire into the histories of the apparently autochthonous cases. The condition suggests an interesting epidemiological problem whose study should now commence with the seemingly early development of the infection in the United States. In view of the high resistance of the cysts to chemical reagents and disinfectants and the high degree of vitality of coccidial cysts in general, the parasite is far more dangerous from the enidemiological point of view than the other protozoa of man.

7. Luminal Contrasted with Bromide in Epilepsy.—F. Golla has observed a total of 125 cases of epilepsy for a period of not less than eighteen months. The results show that of these 36 cases were either not improved or deteriorated under luminal treatment, while the remainder did better under luminal than under bromide. The cases most beneficially affected by luminal were those occurring at frequent intervals, and the cases least affected were those whose fits occurred in bouts at considerable intervals of time. Golla hesitates to believe that luminal exercises a selective action on those forms of epilepsy in which the fits occur with the greatest frequency; it is more probable that a class of epileptics exists which is more refractory to bromide treatment than others; such a class would obviously show the greatest number of fits when treated by bromides, at the same time these patients are not less susceptible to luminal than their fellows, and consequently it is with these cases that the drug shows its most marked effect. The doses of luminal employed rarely exceeded six grains a day of the sodium salt. The drug is as a rule well tolerated and most patients found that they were brighter and more cheerful after a change to luminal from bromide treatment. In twelve cases, however, the patient complained of giddiness and drowsiness. By reducing the dose of the drug toleration was secured in all but four cases. There has in no instance been any signs of the formation of a drug habit, and suspension of the treatment has never given rise to any disturbance. There is a tendency in all cases for the number of fits to increase slightly during the first two months of treatment. The cases suffering from diurnal fits showed a startling superiority of luminal over bromide treatment.

2. Periarteritis Nodosa.—Morris Manges and George Baehr report a case which is unique even for this rare disease, since it is one of the few in which the diagnosis was made during life. This has been done in four other cases, in only one of which has the diagnosis been verified at autopsy. The patient, a man 39 years of age, was admitted to the hospital apparently suffering from an acute abdominal condition, for which an exploratory laparotomy was performed. This revealed periarteric nodules in the mesentery, all the arteries in the mesentery and pancreatic region being involved. Similar nodules were found in the intestinal wall. The nodules were at once recognized as those of periarteritis nodosa. During the two months following the operation the patient became much improved. The only new symptom was failing vision, due to a fibrinous exudate on the temporal side of the optic nerve heads. This was associated with a low-grade nephritis. He was readmitted to the hospital about three months after the operation. At this time the only nodules that could be found were several along the right temporal and brachial arteries. No other nodules developed during the remainder of his life, which terminated with a chronic bronchopneumonia and advanced nephritis. Detailed autopsy findings and pathological studies are presented. The case is remarkable because the vascular lesions found at autopsy represent the end stage of a periarteritis nodosa, in which the acute periarterial inflammatory process had long subsided and the disease was progressing toward healing. Death occurred from renal insufficiency due to the gradual atrophy of tubules and replacement fibrosis interstitium consequent upon the gradual and progressive reduction in the circulation through the diseased renal vessels. Only one other case of similar nature is recorded in which all the arterial lesions found at autopsy had advanced to the stage of healing. This case was reported by Spiro. From the standpoint of etiology the case is important because it gives very positive support to the contentions of those writers who maintain that syphilis is not the cause of the disease. Two Wassermann tests were made, one early and the other late in the course of the disease; both were negative, and nothing of a syphilitic character was found in any of the pathological examinations. All the evidence that has been presented would indicate that the disease is of an infectious nature, the cause of which is as yet unrecognized, and which for some unknown reasons attacks the walls of the medium-sized arteries, with a predilection for the mesenteric, renal, hepatic, pulmonary, cardiac, and cerebral vessels, as well as those in the skin and muscles of the extremities. From the clinical side the case is of interest because of the occurrence of abdominal symptoms simulating an acute surgical condition. This can well be understood when it is recalled that the branches of the celiac axis are the most frequent site of the lesion.

8. Ozena and Its Relation to Tuberculosis.—Fred H. Linthicum calls attention to the fact that ozena, though not an uncommon disease, has been relegated so strictly to the sphere of the rhinologist and the laryngologist that it is but little known outside of these specialties. He sets forth evidence and reports a number of cases pointing to the frequent association of tuberculosis and ozena together with some experimental work done on the subject in the department of laryngology of the Johns Hopkins Hospital. The lesions of ozena are confined to the mucous membranes of the nose and pharynx and may extend to the larynx. They are characterized by the formation of greenish black crusts, with a sickening odor. While the writer has found an acid-fast bacillus in the nasal secretions of ozena, it is not identical with the tubercle bacillus. Nevertheless, because of the frequent association of the two conditions, he decided to try tuberculin treatment in ozena. He succeeded in collecting nine patients with ozena, seven of whom consented to take the tuberculin treatment. All of these showed improvement after longer or shorter periods of treatment, though in one instance the initial improvement was followed by relapse. By improvement is meant cessation in the discharge and odor and a betterment of the general condition. In none of the cases was the atrophy in the nose affected. In some the sense of smell returned to a certain extent.

10. Studies on the Dosage of Digitalis in Children.—Hugh McCullough and Wayne A. Rupe have attempted to determine the amount of tincture of digitalis that is necessary to produce certain effects on the heart of children in order to establish whether the relationship between body weight and dosage that has been recently established for adults is directly applicable to children, or if not, what modifications are necessary in order to base the dosage of the tincture of digitalis on the body weight of children of various ages and weights. From observations conducted on thirty-six children they conclude as follows: (1) The results show that between eight and twenty kilos of body weight, or up to the approximate age of four years, children respond more readily to digitalis than do children above this weight and age. It would seem that older children with normal hearts require a larger amount per unit of body weight than is necessary to produce an effect in adults with heart disease. (2) There is considerable variation in the amount of digitalis necessary to bring about a response in the hearts of children. (3) Vomiting was noticed to be one of the early signs of the effect from digitalis administration, often occurring before there were any alterations in the electrocardiogram. Changes in the electrocardiogram were not constantly found in all the cases in which a digitalis effect was obtained. The most common change observed in this group of children was the appearance of a sinus arrhythmia. Alteration in the size and direction of the T wave occurred in a small number of cases.

1. An Analysis of Operatively Demonstrated Lesions of the Gall-Bladder and Bile Ducts from the Standpoint of Early Diagnosis.—Royale H. Fowler asserts that there is no doubt that the near and remote results of disease of the biliary tract should be classed as sequels of hematogenous or lymphogenous infection. The various lesions are but degrees in a process of reaction to irritants, not definite entities, but represent a sliding scale of infective changes due to varied virulence and type of the organism and to a variable resistance on the part of the gall-bladder itself. A résumé of cases is used to illustrate the terminal pathology of the gall-bladder and bile ducts. This shows that (1) the average age of these patients at operation was 42 years, 4 months; (2) the average duration of symptoms referable to the stomach before operation was 4 years and 10 months; (3) the average duration of symptoms referable to the gall-bladder before operation was about 3 years; (4) the average age at which infection of the gall-bladder was known to have existed was 30 years and 5 months. These cases may eventuate in cancer

if allowed to go untreated. In cholecystitis or the pregallstone stage there is one treatment—cholecystectomy; the mortality should not be over 2 per cent. Then there will be no recurrence. In the second stage, for stone limited to the gall-bladder, there is one treatment—cholecystectomy. The mortality should also be low and the postoperative morbidity *nil*. These operations in general are performed on young adults. In the third stage, that of terminal complications, the patients are more advanced in years, there may be cardiorenalvascular changes which have occurred in the long interval since the onset of gall-bladder infection. Here one must consider cholecystectomy whenever possible, drainage operations, and anastomsis. The mortality in this stage may be 15 per cent. A cure may be expected in more than 70 per cent. of cases by cholecystectomy. More than 20 per cent. will be improved. The 10 per cent. of failures should be investigated further.

5. Schneider's Test in Pernicious Anemia.—E. S. Platou reports a case in which tentative diagnosis of pernicious anemia and pulmonary tuberculosis was made. Believing that the Schneider test might throw light on the diagnosis, this test, slightly modified, was employed. The values obtained from the test in a large series of extractions has established the following facts: (1) That the presence of urobilinogen in the bile in considerable amounts is a pathological finding. (2) That urobilin does not occur in the duodenal contents of a normal fasting adult in values exceeding 1000 units of dilution. (3) That diet has no influence on the values of either pigment. The test probably has its greatest usefulness clinically in differentiating cases of pernicious anemia from obscure cases of severe secondary anemia resulting particularly from carcinoma and hemorrhage. In the former the values generally run extremely high; in the latter they are not increased above the normal. In the case reported values of 4000 units on one occasion and 4800 on another were of distinct advantage in the diagnosis in view of the patient's youth (18 years) and the absence of neurological findings.

2. On Certain Variations in the Form of the Human Eleetrocardiogram.—Edward P. Carter and Francis R. Dieuaide summarize their observations on variations in the amplitude and direction of the waves of the QRS complex as follows: (1) Variations in the amplitude (including extremely low values) and direction of the QRS complex and transient notching of R and S in the human electrocardiogram occur not only in lead III, but also not uncommonly in the other leads, especially in records of abnormal hearts. (2) These peculiarities are dependent upon the relation of the electrical axis of the heart to the planes of the leads. Tables are given showing the angles at which conspicuous variation is present in each lead, and the angles between which fairly marked variation occurs in each combination of two leads. The terms "stable" and "unstable" are suggested with reference to the variability of the leads. (3) Variations are due in some instances to shifts in the relative position of the heart; in others to pathological changes in the bundle tract and to alteration in the relation between the ventricles; in a great many others to causes at present unknown.

3. A Statistical Note on Epidemic Encephalitis.—Raymond Pearl presents a careful and exhaustive analysis of the figures on the incidence and mortality from epidemic encephalitis in New York City during the years 1919 and 1920. These data, he points out, are the most extensive in existence and fairly represent about all the basis of a statistical character which exists for forming an intelligent opinion *now* about the statistical features of this important disease. The conclusions he reaches are as follows: (1) In the year 1920 the case incidence of epidemic encephalitis increased in New York City nearly five-fold over 1919. At the same time the case fatality rate increased from 26 per cent. of the attacked to 37 per cent. of the attacked. It is believed that this increase in case fatality rate is a real phenomenon; it is certainly statistically significant. (2) The seasonal incidence, as judged by monthly distribution of cases was significantly different in 1920 to what it was in 1919. (3) The peak of mortality in an epidemic outbreak may be expected to occur from 23 to 37 days *after* the peak of case incidence (morbidity). (4) There is a significantly larger proportion of males among the attacked than there is in the general population, or, put in another way, males are especially susceptible, to a statistically significant degree. (5) Deaths occur among males no more frequently in comparison with females than would be expected from the normal proportions of the two sexes in the population at large. (6) The disease is not more likely to attack either males or females at one age than at another. The age distribution of attacked cases, in other words, does not significantly differ in either sex from the age distribution of the general population. (7) The age distribution of deaths does not differ significantly in both sexes from the age distribution of the population. There appears to be a definite tendency for the disease to be more fatal in the higher age groups.

7. The Capacity for Phagocytosis Shown by Polymorphonuclear Leucocytes in Dead Animals and After Preservation in Salt Solution.—Howard B. Cross describes observations upon the polymorphonuclear leucocytes and other cells made under the most varied circumstances. The suspensions were sometimes kept in the refrigerator, no other precaution was observed to preserve the cells, and no special effort was made to prolong their life. It was found that polymorphonuclear leucocytes sometimes take up and digest bacteria within the body after death. In one instance these phagocytes remained alive within the body for eleven days after death and were still capable of energetic phagocytosis. Leucocytes suspended in physiological salt solution, provided a trace of serum be present, may remain alive and manifest considerable phagocytosis for a considerable length of time. Marked changes in the temperature of the phagocytes after separation from the body do not destroy and often do not alter the capacity of the leucocytes for phagocytosis. Polymorphonuclear leucocytes which had retained their functional capacities for three days within the dead body were removed and after being kept several days in a test-tube were still capable of energetically phagocyting bacteria. Phagocytes from the blood and exudates seem to possess equal tenacity of function. Human leucocytes are capable of sustained independent existence.

7. Case Reports of Gonorrhea Treated with Vaccines. S. Sterling Stahl.

2. Pylorie Relaxation and Inhibition.—W. H. Foreman states that pyloric relaxation and inhibition are influenced by: (a) Organic obstructive disease at the pylorus, or (b) functional interference due to disturbance in the upper or lower gastrointestinal tract or reflexes from disturbed function in other structures. Functional disturbances at the pylorus are frequent. Organic disturbances are relatively rare. Motor, secretory, and sensory symptoms in the stomach, due to functional disturbance of the pylorus, are very similar to gastric symptoms in organic disease at the pylorus. The roentgenogram is of relatively little value in the diagnosis of disturbances of pyloric relaxation and in-

hibition since the diagnostic symptoms are chiefly motor. For the same reason the fluoroscope is of great value. Disturbed secretion is an incident of functional or organic pathology in or out of the stomach. However, the presence or absence of free acid in the stomach considerably modifies gastric function and influences healing of gastric or duodenal ulcer.

Le Progrès Médical.

Acute Hyperthymia.—According to Benon, who gives several case histories, acute hyperthymia without delirium appears in subjects who have undergone some painful moral experience. There is present a fixed idea with an intense development of emotional or affective manifestations. It was seen in subjects who were forced to enter the ranks during the war, leaving behind either young children or important business interests, there being no one available to take over the responsibility. But it is, of course, possible that this factor was only casual in its operation, and that the condition was endogenously motivated. Under the conditions just mentioned other factors could certainly coöperate, as military rigors. This type of psychosis resembles simple melancholia, and usually passes for such, but the author makes a distinction. The fugues exhibited by these patients are not readily accounted for. The most plausible explanation is that they rest on hallucinations. They are amnesic in character, so that the subject cannot supply self-analysis. The author, although commonly using the term hyperthymia for these cases, speaks on one occasion of an "affective dysthymia" as defining the condition. The term hypothymia is applied to dementia præcox. Moral shock, fixed idea, periods of amnesic ambulatory activity, serve chiefly to differentiate this condition from other psychoses and psychoneuroses. Recovery often follows.

Le Progrès Médical.

August 20, 1921, xlix, 34.

Hypotensive Action of Tincture of Garlic.—Loeper and Debray refer to certain uses of garlic in medicine—in pulmonary tuberculosis, and other pulmonary infections. The common method of exhibition is by inhalation. They have recently tested its use by the mouth in doses as high as 40 drops daily. There were no untoward effects. The tincture is eliminated by the lungs much more slowly than natural garlic, the breath being impregnated with the drug for some hours. In old pulmonary sclerosis this period is considerably prolonged. The same retardation is seen in stasis and cirrhosis of the liver, a fact which has been utilized in testing the hepatic functions. In the present paper the authors are interested chiefly in the hypotensive action of the drug, which was in evidence in numerous cases of high blood pressure tested for the occasion. The fall is not striking, but in the very high tensions there is a considerable lowering which in a given case might be decisive. The period of latency is 30 to 40 minutes, and the favorable effect is often apparent even on the following day. We are not so well supplied with hypotensives that we can afford to ignore this new addition which will doubtless find employment despite the unesthetic odor which it imparts to the breath.

La Presse Médicale.

August 17, 1921, xxix, 66.

Sixty-six Gastrectomies for Cancer.—Olivier reports this series, the type of operation being the Billroth II. Ten patients failed to withstand the intervention, this including all fatalities within the operative period. In one-half death resulted from post-operative pulmonary complication. There were three deaths from shock and two from peritonitis. It should be stated that this series of 66 cases covers a period of 26 years, dating from 1895. Of the entire series 18 have been operated on during the past three years under local anesthesia. During the latter short period there has not been a single fatality. But in dissociating the series it makes the mortality up to 1918 no less than 25 per cent., while this is offset by the zero mortality of the recent series. Of the 56 patients who withstood the intervention 41 are dead and 13 are living, two others being unaccounted for. Of the 41 decedents 16 died during the first post-operative year and 13 others before the third year. The remaining 12 died at various intervals beyond three years—all the way from four to twenty years. Since no less than seven patients survived the five-year limit, they may with qualifications be added to the 13 actual survivors. This is true especially of three who survived from eleven to twenty years, dying of intercurrent disease. On the other hand, a number of the actual survivors have been operated on too recently for statistical purposes. The author claims 27 per cent. of three-year survivors.

Rectocolic Rupture from Compressed Air.—Jean contributes an exhaustive article on this subject, the literature of which goes back to 1911, when Lenormant in France and Andrews in the United States published the known material to date. There are now upon record at least 25 cases. Since most of these run to type the two recent observations of the author, both in 1920, will serve to visualize the affection. The first subject was a boy of 15 who worked with rock drillers. One day he had an altercation with a driller, who in anger or rough play directed the nozzle against the boy's anal region. The pressure was 26 atmospheres. The nozzle did not even touch the boy's person, but soon after he collapsed from pain due to distention of the bowel with gas and rupture, and was taken to the hospital. The distention was colossal, and vital functions were almost suspended. After antishock treatment had caused some improvement laparotomy was at once performed, as it was only too evident that intestinal perforation had occurred. So great was the damage done that an extensive resection of the lower bowel was found necessary. The patient recovered. The second case in a man of 36, a worker, was purely accidental. The man was seated crosswise on a bench with the anal region jutting over the end. Beneath was the hose, sharply kinked. A rupture at the kink caused a powerful discharge of compressed air against the perineum. There followed colossal distention of the abdomen and subcutaneous emphysema. Laparotomy with resection of a portion of colon was followed by recovery.

Journal de Médecine de Paris.

August 20, 1921, xl, 23.

Prophylaxis of Cancer.—Pauchet deals especially with the rôle of intestinal stasis in the genesis of cancer of the stomach. In general there are three causes of cancer, two of which we know, while the third we are ignorant of. The two known factors are local irritation of many kinds on the one hand and some kind of chronic intoxication on the other. The third factor, which we do not know, may be a living organism or cellular vice. In cancer of the stomach the local cause is usually an ulcer and the accessory factor constipation and autointoxication. The latter as a rule goes back to infancy—there has always been a stercoremic element. Some prefer to call the condition cholemia. It is for the most part silent. In youth at least the subject is healthy and vigorous. Only by palpation do we bring out the presence of colonic stasis. Even in later life the subject remains at times unconscious that anything is wrong with him. In many cases, however, autointoxication is clearly in evidence. In recent years it has been easy to demonstrate the presence of stasis with the *x*-ray. Naturally the various clinical manifestations of intestinal stagnation, as outlined by Lane and others, may be more or less in evidence. Secondary enterocolitis may lead directly to cancer of the bowel. The author carefully outlines the relationship between stasis and local irritation on the one hand and the development of colonic cancer on the other. The small bowel is relatively immune and stasis is not a factor here, for its liquid content protects it from irritation by solid particles. There are mechanical reasons why stasis and ptosis of the colon favor the development of juxta-pyloric ulcer, both gastric and duodenal. These are bound up with an exaggeration of the normal duodenojejunal kink.

Book Reviews.

THE INTERNATIONAL MEDICAL ANNUAL. A Year Book of Treatment and Practitioner's Index. 1921. Thirty-ninth year. Price, $6.00. New York: William Wood and Company.

AFTER looking through this volume one is amazed at the enormous amount of information which it contains. It seems that the editors and contributors have gleaned the medical literature and abstracted what was worth while, and here present it in handy form to the busy practitioner and student. There is no physician who would not benefit by a perusal of several pages of this volume. Among the articles which have attracted our attention may be mentioned those on the Chemistry of the blood; Cytology of the blood; Cerebrospinal fever, and the meningococcus carriers; Influenza, and the value of prophylactic inoculation; Smallpox, with its new method of treatment by applying a saturated solution of potassium permanganate; Arterial tension, and the method of measuring it; Heart disease, and the newer methods of examination by the electrocardiograph and skiagraph; Psychotherapy; Epilepsy; Encephalitis lethargica; Diabetes; and Deficiency diseases. The book is of handy size, is well printed, has ample illustrations, and is equipped with a good and serviceable index. The references to the bibliography are of service, and are placed at the end of each article; they take up but little room, and do not interfere with one's reading. Altogether, this is one of the most useful publications of the year.

FRENCH-ENGLISH MEDICAL DICTIONARY. By ALFRED GORDON, A.M., M.D. (Paris), Late Associate in Nervous and Mental Diseases, Jefferson Medical College; Late Examiner of the Insane, Philadelphia General Hospital; Neurologist to Mt. Sinai, to Northwestern General, and to The Douglas Memorial Hospitals; Member of the American Neurological Association; Fellow of the American College of Physicians; Corresponding Member of the Société Médico-Psychologique de Paris, France; Member of the American Institute of Criminal Law and Criminology, etc. Price, $3.50. Philadelphia: P. Blakiston's Son & Co.

THIS book will be found a useful aid by readers of French medical works whose knowledge of the language is not very profound. The vocabulary seems to be quite full, fuller than is necessary, indeed, since it includes many terms, like liquor sanguinis, phlegmasia alba dolens, and others, which are no more French than they are English. The English equivalents are satisfactory and the book may be commended to readers of French treatises on medicine, but we would warn the user not to trust to the pronunciation of the French words as here given—it is horrible! SSehssahmohéed is, we are told, the way a Frenchman pronounces sésamoïde; ssrehng is seringue; skvahméh is squameux; nehpohzshéha (but this surely must be a misprint) is nephogène; and so on all through the book. The dictionary could be greatly improved by omitting the figured pronunciation.

THE ALLEN (STARVATION) TREATMENT OF DIABETES. With a Series of Graduated Diets. By LEWIS WEBB HILL, M.D., Junior Assistant Visiting Physician, Children's Hospital, Boston; Alumni Assistant in Pediatrics, Harvard Medical School, and RENA S. ECKMAN, Dietitian, Massachusetts General Hospital, Boston, 1911-1916. With an Introduction by RICHARD C. CABOT, M.D. Fourth Edition. Price, $1.75. Boston: W. M. Leonard, 1921.

THE Allen treatment of diabetes is known to most physicians by name, but to many by name only. Those who wish to inform themselves of the rationale of the method and the details of its execution (and all should for, according to the experience of those who have given it an extensive trial, there is no better treatment of diabetes known today) cannot do better than study this little book. It will take but an hour of their time and it will be an hour well spent. In addition to a description of the method and a number of case reports, the book contains a series of graduated diets which will serve as guides for the feeding of the patient, various recipes for palatable dishes for the diabetic, and a statement of the starch content of a number of "diabetic foods" on the market.

SURGERY, ITS PRINCIPLES AND PRACTICE. By Various Authors. Edited by WILLIAM WILLIAMS KEEN, M.D., LL.D., Emeritus Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia. Volumes VII and VIII and Desk Index. Price $25.00. Philadelphia and London: W. B. Saunders Company, 1921.

THESE two volumes are supplementary to the well-known system of surgery in six volumes, the publication of which was completed in 1913. Since that time there has been a very large addition to our surgical knowledge, derived in greatest measure from the war experience, and that, in addition to the natural increment in seven or eight years, is embodied in these new volumes. The contributors to the two volumes, of over 1800 pages, number seventy, many of them men who saw service in the British or American armies during the war. The articles are not all dealing with new subjects, for many of them are merely supplementary to those appearing in the earlier volumes, bringing the matter there contained down to date. The illustrations, about a thousand in number, are excellent, most of them being original. Those who possess the earlier volumes of this work will find these two volumes and the new Index to the complete work indispensable. This index is very full and satisfactory. The preface, containing a brief review of the war lessons, the farewell to the contributors, and remarks concerning *fides germanica*, will be read with interest.

DIAGNOSTISCHE UND THERAPEUTISCHE IRRTÜMER UND DEREN VERHÜTUNG. INNERE MEDIZIN. Zwolftes Heft. Krankheiten des Gehirns und des Verlängerten Marks. Von Geh. Med.-Rat. Prof. Dr. E. MEYER. Price, 33 M. Leipsig: George Thieme, 1921.

THE General Section of this work has to do with the chief symptoms of intracranial disease, as headache, vertigo, etc., and numerous syndromes of the motor, sensory and special sense nerves. There are special chapters on speech disorders, reflex disturbances and localization. The special section has eight chapters on the following subjects: Meningitis, circulatory disturbances, encephalitis, cerebral lues, progressive paralysis, brain tumors, hydrocephalus and congenital defects with a concluding one on the medulla and pons. One would naturally expect to find a great number of case histories to illustrate the possibility of diagnostic errors, but only a few are cited. The scope of the book is largely that of differential diagnosis but more stress than usual is laid on the therapeutic blunders.

MANIC-DEPRESSIVE INSANITY AND PARANOIA. By Professor EMIL KRAEPELIN of Munich. Translated from the 8th German Edition of the "Textbook of Psychiatry," by R. MARY BARCLAY, M.A., M.B. Edited by GEORGE M. ROBERTSON, M.D., F.R.C.P. (Edin.), Professor of Psychiatry in the University of Edinburgh, etc. Price 21 shillings. Edinburgh: E. & S. Livingstone, 1921.

THIS work is a companion volume to the same translator's "Dementia Præcox and Paraphrenia," the two books making up the total of Kraepelin's textbook on the endogenous psychoses. The editor does not allude to the earlier English version edited by Johnstone, which went through an edition as recently as 1913, but this was made originally from the second German edition while the present is from the eighth German.

BALLIÈRE'S NURSES' COMPLETE MEDICAL DICTIONARY. Edited by CONSTANCE M. DOUTHWAITE,, Member of the League of Nurses of St. Bartholomew's Hospital, London. Second Edition. Price, $1.25. New York: William Wood & Company, 1921.

THIS little volume will be welcomed by nurses. It gives the pronunciation and meaning of probably all the technical terms which a nurse is likely to meet; it also includes the chief symptoms of the different diseases, and the nursing treatment indicated in these conditions. At the end of the book is an appendix giving the meaning of various abbreviations, tables of weights and measures, and a very complete outline of the symptoms and treatment of the different forms of acute poisoning. We have examined several of the pages with care, and have been struck by the general accuracy and completeness of the book.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held March 4, 1921.

DR. SEWARD ERDMAN IN THE CHAIR.

Retroperitoneal Tumor Causing Obstructive Jaundice.—Dr. JOHN MUNN HANFORD presented this patient, a man 53 years of age, who first came under his observation a little over two years ago. He gave a history of steadily increasing jaundice, loss of twenty pounds in weight, dark urine, and clay-colored stools. The jaundice varied in degree from time to time but never disappeared entirely. Physical examination revealed flabbiness, and other evidences of poor nutrition. A firm, movable, good-sized, globular mass was felt in the right upper quadrant. The finger could be pressed in deeply between the mass and the liver edge. The liver edge seemed normal though a little lower than the normal level. The *x*-ray of the stomach suggested a new growth of the pyloric region. The blood clotting time varied from four to 13½ minutes. The Wassermann was negative. The blood was otherwise relatively normal. The stools showed fat and fatty acid crystals. The clinical diagnosis was carcinoma of the pyloric region of the stomach causing obstructive jaundice. Operation February 24, 1919, through a transverse incision, revealed a movable, ovoid, cystic, though firmly encapsulated, tumor located in about the midline, in front of the second and third lumbar vertebræ, behind the head and neck of the pancreas, which, together with the pyloric end of the stomach, the duodenum, and the common bile duct were pushed forward. The gallbladder was quite distended but otherwise apparently normal. The bile was cultured and a non-hemolytic *Staphylococcus aureus* grown from it. The first and second portions of the duodenum and the head of the pancreas were adherent to the surface of the tumor. No lymph glands were found enlarged. The right kidney was normal. The posterior surface of the mass seemed too densely adherent to the vena cava to warrant removal. It was first thought to be a cyst, but no fluid could be aspirated. Instead a bit of pale, soft, pinkish tissue, resembling that of a cellular malignant neoplasm, was aspirated from the center of the mass. A cholecystduodenostomy by suture was done, and the wound closed. The post-operative course was very satisfactory and the man had been improving apparently ever since. The jaundice quickly disappeared and he had regained his weight and strength. He now had a small umbilical hernia and there was an impression of slight increase in the size of the mass on abdominal examination. The pathologist's diagnosis upon the tissue from the center of the mass was round-celled sarcoma. This diagnosis had been confirmed by several well known and expert pathologists. The case was presented as an instance of a rather unusual tumor which had proven less malignant than the pathologists indicated, and was presented also for advice as to its further treatment. Since removal seemed to be hazardous he felt that *x*-ray therapy was indicated and that perhaps it should have been used from the time of his post-operative convalescence.

Inflammatory Tumor of the Cecum in a Child.—Dr. EDWARD D. TRUESDELL presented this case, a child admitted to St. Luke's Hospital, August 2, 1920, with the diagnosis of acute appendicitis. The history was that the child had become sick on the day of admission with pain in the right lower quadrant, nausea, and vomiting. There had been three similar attacks during the past few months, accompanied by pain in the right lower quadrant and vomiting. A mass could be felt in the right lower quadrant resembling a movable kidney. The mass was smooth, freely movable and slightly tender. A cystoscopic examination was made and the kidneys found to be in their normal position. The leucocyte count was 10,700, and the differential count showed 78 per cent. polymorphonuclears. The preoperative diagnosis was appendicitis with abscess, probably of the movable type. At operation the tumor was found to involve chiefly the anterior wall of the cecum and the lower portion of the ascending colon. There were no enlarged lymph nodes and the appendix was seen in the lower portion of the mass. There was nothing to indicate the diagnosis of tuberculous tumor, and it did not appear to be malignant, hence it seemed fair to remove the appendix rather than to incise and anastomose the bowel. The appendix was only 1¼ inches long and much thickened, and on section showed a little mucopurulent pus in the center. The pathologist reported that the condition was that of chronic appendicitis. The wound healed primarily. The patient was examined on August 22, eighteen days after the operation, and the tumor found to be decidedly smaller than before operation. Another examination was made on September 8, after the patient had been in the country for two weeks, and a further decrease in the size of the tumor noted. At examination in January no evidence of any tumor could be found. The pathologist's report showed no evidence of tuberculosis. The patient's general condition had improved very materially since the operation. He believed the patient had an inflammatory induration of the cecum following upon chronic suppurative appendicitis.

Dr. CHARLES EVERETT FARR said he had been present at the operation and he wished to congratulate Dr. Truesdell on his good judgment in not attempting to do anything to the cecum, although the tumor had the earmarks of a tuberculous neoplasm.

Dr. ROBERT T. MORRIS said the clinical history in this case was strikingly suggestive of tuberculosis. With an ordinary inflammatory condition recovery would be more rapid than it was in this case. Here it was about as long as one would expect if the condition were tuberculous and recovery instituted by hyperleucocytosis excited at the time of operation. He had had a number of these cases in which he had not operated, except to remove the appendix. He had then instituted general treatment for tuberculosis. He had never excised the cecum in these cases and the patients made a good recovery from the local condition in about the same length of time that this patient did. Some of the patients had developed other phases of tuberculosis subsequently.

Dr. EDWIN BEER said this group of cases was a very important one because of the difficulty in diagnosis. He had had at least four cases similar, and one absolutely identical with the case presented by Dr. Truesdell, and in that particular case all the physicians who examined the case thought it was a case of sarcoma of the kidney. There was a movable tumor filling the right flank posteriorly and anteriorly. The only symptoms evident were right iliac pain, nausea and slight temperature which had been going on for months. The differential diagnosis rested between a retroperitoneal inflammatory condition and a tumor of the anterior portion of the kidney. The patient presented by Dr. Truesdell was an absolute counterpart of this case of retroperitoneal inflammatory tumor. In all of his cases Dr. Beer said rapid recovery followed removal of the appendix without touching the cecum.

Dr. SEWARD ERDMAN said he had the feeling that inflammatory swellings in the region of the cecum of long duration were in the large majority of cases tuberculous. He recalled that he had reported six cases of such tumors, five of which were shown to be tuberculous by pathological examination, and in the sixth case it was still questionable whether or not the condition was tuberculous. That tuberculosis could not always be demonstrated in these cases was not to be wondered at when one considered that 4 or 5 inches of a tuberculous cecum might be removed and a thousand sections examined without finding definite tubercles. One frequently found a marked inflammatory reaction around an acute or subacute appendix, and this often melted away after the appendix was removed. But where the tumor was of the hyperplastic tuberculosis type, encroaching on the lumen of the bowel, he believed that resection of the cecum was definitely indicated.

Resection of Elbow Joint for Ankylosis.—Dr. REGINALD H. SAYRE presented this patient, a young woman who had come under his observation about a year ago with an ankylosis of her right elbow. Dr. Sayre presented *x*-ray plates showing the condition at that time. The arm was so stiff that she was unable to use it. She was very desirous of having a movable joint because a stiff elbow greatly interfered with her

work as a dressmaker. He therefore made an incision, pushed back the ligaments, sawed off the lower end of the humerus, scooped out an apology of a cavity for the ulna, covered the humerus with fascia from the outside of the arm, and thus reconstructed a joint. The ligaments were too loose and she was left with a lump on the outer side of the elbow, but function was remarkably good. He expected at a future time to operate again to add the element of supination and pronation now absent, owing to ankylosis between the radius and ulna.

Ankylosis of the Elbow and Its Treatment by Arthroplasty.—Dr. WILLIAM R. MACAUSLAND of Boston made a lantern slide demonstration of his operation for ankylosis of the elbow. There were two methods of dealing with this condition: (1) excision which gave good motion but not good elbow stability, and (2) arthroplasty. Murphy had devised a method of arthroplasty by which the biceps fascia or fat was placed between the bone surfaces of the newly-formed joint. The objection to this method was that there was likely to be a sloughing of the biceps region from which the fascia or fat was dissected and at times there was a necrosis of the fat graft. The object of arthroplasty was to obtain a stable gliding joint. The method to be demonstrated he had used in 34 cases with more satisfactory results than were usually obtained in ankylosis of the elbow. The operation was as follows: A curved incision was made from one condyle to the opposite condyle passing over the middle of the olecranon. The skin and superficial fascia were dissected up to a base line at the end of the incision and then retracted. The skin and fascia were dissected back a little on both sides and on the forearm end of the incision. The ulnar nerve was dissected out of its sheath and gently retracted with gauze. A straight incision was made down to the bone over the condyle so as to elevate en masse the tissue that would serve as a new capsule. The olecranon was then sawed across and separated. The capsule, fascia, and ligaments were dissected back to allow the lower end of the humerus to protrude out of the wound. A new intercondylar surface was formed as nearly as possible like the normal one. A shoemaker's rasp was used to file off the new surface. A piece was then removed corresponding to the olecranon fossa in the normal humerus. The olecranon was then trimmed so as to take the new humeral head. The joint surfaces should fit accurately before the fascia was applied. If too much of ends of the bone was removed a flail joint resulted. The fascial flap was then dissected from the right leg on the outer side of the thigh. This fascia free from all fat was placed about the new humeral condyles so that all rough surfaces were covered, and was held in place by a purse-string suture. The fascia, ligaments and old capsule were then sutured with chromic gut. The olecranon was sutured with double chromic gut and the skin closed with silk-worm gut.

Dr. PERCY WILLARD ROBERTS said the Section was much indebted to Dr. MacAusland for this demonstration. Last winter he had had three or four cases at his clinic at the Hospital for the Ruptured and Crippled in which the results had been very unsatisfactory. This led him to ask to be invited to Boston to see how Dr. MacAusland performed his operation. He had been very much impressed with its advantages. In the first place the approach to the joint was excellent, and, secondly, every step was well worked out for the purpose of obtaining a smooth sliding joint. He had especially been impressed with the careful way in which the procedure had been thought out. It was a relatively short operation, and while he had not seen the results he had talked with those who had, and they were in accord in stating that Dr. MacAusland was very conservative in his claims. He obtained not only motion, but the very important factor—stability. Speaking of using a shoemaker's rasp for smoothing off a bone surface, those who were doing bone work where smooth surfaces were desirable would do well to invest 25 cents in a shoemaker's rasp. He had been using one in his operation for hallux valgus. Dr. MacAusland's operation, as a whole, was just what he had shown it to be on the screen; it was well planned and well worked out.

Dr. SAYRE emphasized what Dr. MacAusland said about the advantages of the fascia from the thigh. He had tried using a flap taken near the ankylosed joint, using a flat flap taken from the fascia of the biceps, and recalled one case in particular in which it had been very doubtful for some time whether the skin flap would not slough. Dr. MacAusland's plan of using the fascia from the thigh was much better as there was less likely to be sloughing and necrosis. It was also much better to form the deep cavity for the head of the ulna. There was less likelihood of the ulna sliding out if the cavity was constructed in its original shape in the end of the humerus.

Dr. WILLIAM L. SNEED stated that after hearing Dr. MacAusland several years ago he had become very much interested in this operation, and had been thinking of one other phase of the matter, with reference to pronation and supination. The idea had occurred to him that if the orbicular ligament and periosteum were saved and a portion of the head of the radius taken out opposite the lesser sigmoid cavity of the ulna, and this ligament and fascia sutured over to the head of the radius, it might be possible to secure pronation and supination in a way that did not interfere with stability of the joint secured by the operation as Dr. MacAusland performed it.

Dr. MACAUSLAND said there were two types of cases in which this operation could be used—traumatic and infectious. The traumatic was the best type for operation. In the infectious type one had to wait until the infection quieted down and the joint became ankylosed. In a tuberculous case one never knew whether the infection was eradicated, for years after one might still find a walled-off focus. In non-tuberculous infections one might operate at a time well beyond the period when any dormant infection might be present. Our views in regard to operating after infection had been greatly changed by our war experience, and he thought now that operation should be delayed for two years following bony ankylosis. The 34 cases in which he had performed this operaton had been ankylosed for years. Usually he had not gotten the cases until eight or ten years after ankylosis had taken place. Under no conditions would he operate on an infectious case under two years. Whether an arthroplasty should ever be done on a tuberculous elbow was a question which had provided a great deal of discussion. He had done such an operation in one instance some five years after infection seemed to have subsided. He had questioned whether it was the right thing to do, but inasmuch as the results had been good, Dr. Whitman said he was justified in doing the operation. Certainly one should not perform such an operation under five to eight years after the infection had appeared to subside. As to Dr. Sneed's remarks about pronation and supination, he had decided that if he could get motion with the thumb up that was all he would attempt to secure. He had not aimed at the refinements, the patients had not asked for pronation and supination, and he had never offered it. However, he approved of the idea.

The X-Ray Diagnosis of Tuberculous Glands of the Neck.—Dr. JOHN MUNN HANFORD read this paper, which was illustrated by lantern slides. He stated that his reading and observation had given him the impression that calcification of tuberculous glands of the neck had failed to attract its full share of attention. There was an almost unanimous agreement among pathologists that calcification in a cervical lymph gland, or in tissue associated with a cervical lymph gland indicated tuberculosis, and nothing else. Simple lymphadenitis, Hodgkin's disease, lymphosarcoma, carcinoma, cysts of the neck, and other lesions which might be confused with tuberculosis here, did not present calcification or other changes showing increased density in an *x*-ray plate. A calcified artery might give a shadow but this was apparently rare. In the presence of an *x*-ray shadow corresponding in location to definite disease in the neck, this disease might, with almost 100 per cent. of accuracy, be diagnosed tuberculosis. Of *x*-ray plates taken under Dr. Imboden at the Presbyterian Hospital on 31 patients with lesions of the neck, 15 patients showed calcification corresponding to the lesions. Of these 15 patients 7 were proven tuberculous by the microscopic examination of excised tumors. The remaining 8 showed such large circular areas of density as to leave no argument about the diagnosis of tuberculosis. Of the 16 patients who showed no evidence of calcification

in the neck, 12 were proven tuberculous by microscopic examination or by guinea-pig inoculation. Of the other 4, 2 had a definite pulmonary tuberculosis and the other 2 were probably tuberculous. From these findings Dr. Hanford concluded that nearly 50 per cent. of cases of tuberculous lesions in the neck might be definitely diagnosed by the roentgen ray. Whatever the percentage of incidence, evidence of calcification was sufficiently frequent in these cases to warrant the everyday use of the *x*-ray.

Stated Meeting, Held April 1, 1921.

DR. SEWARD ERDMAN IN THE CHAIR.

Unusual Type of Cervical Adenitis.—Dr. EDWARD W. PETERSON presented this patient, a man 29 years of age, who came to the Post-Graduate Hospital in February, complaining of a swelling in the right submaxillary region which he had had for two years. A careful search revealed no focal infection. The glands were involved from the angle of the jaw to the clavicle. It was thought at first that the man had tuberculous adenitis. He was shown for two reasons: First, the type of approach; this was an inverted V-shaped incision which made it possible to clean out the glands from the angle of the jaw to the clavicle; and, secondly, because of the report which came from the laboratory. There were two masses, one about the size of an egg and the other considerably smaller. There was an extensive periadenitis suggestive of the patient's having had too much *x*-ray treatment without success. The report showed that the mass consisted of a conglomerate mass of lymph nodes, densely fibrous, with irregular caseous areas, partly calcified. The mass showed lymph glands partly broken down in one part, areas of irregular nodes, and areas where the cells predominated. There were epithelial cells and a few red blood cells in the tissue. The second specimen showed a similar picture which was not that of tuberculosis. There was very little inflammation and the cells were so atypical that they were suggestive of salivary gland mixed tumor or embryonic rest. The diagnosis of malignant, probably salivary gland tumor, was made. All the pathologists who had seen the section agreed that the tumor was of very malignant type. The patient, however, had gained twelve pounds and felt well. He still had some enlargement of the glands remaining which were very suggestive of recurrence. He was receiving vigorous *x*-ray treatment and it was hoped in that way to control their growth.

Lymphosarcoma of the Stomach.—Dr. PETERSEN presented this patient, a man 53 years of age, who was admitted to the Post-Graduate Hospital in December last. He was at that time very cachetic and anemic. His father died of cancer of the stomach, his mother of pneumonia, at the age of 80. The patient gave a history of having had pneumonia five years ago, and of having begun to suffer from indigestion about a year ago. He was not taking much food because of the vomiting and distress it caused. He had lost about fifty pounds in weight. There was a large mass in the upper part of the abdomen. The Wassermann reaction was negative. The blood count showed red blood cells 1,600,000, leucocytes 6000, polymorphonuclears 68 per cent., lymphocytes 32 per cent., 2 large and 30 small; hemoglobin 60 per cent. It was thought that he had either Hodgkin's disease or carcinoma of the stomach with involvement of the retroperitoneal lymph glands. From the severe cachexia and the size of the mass it was not thought that he had a chance in the world. A left rectus incision was made and the stomach found much enlarged, though the growth had not broken through. Two-thirds of the stomach was resected, removing the growth entirely. There was no involvement of the liver that could be made out. These cases were comparatively rare. In twelve years, Dr. Peterson stated that there had been but one other case of the kind at the Post-Graduate Hospital. Dr. Douglas in an article published in the *Annals of Surgery*, reported three cases, two of which were seen at Bellevue and one at St. Luke's Hospital.

Dr. JOHN DOUGLAS said that Dr. Petersen's case of lymphosarcoma of the stomach was interesting because of its rarity, and also from the standpoint of pathology. Of course sarcoma of the stomach was quite rare in comparison with carcinoma. About a year ago Dr. Douglas had had occasion to look up the literature on this subject when he reported three cases of his own. He collected 230 authentic cases, the majority found at autopsy, though there were some 92 cases operated upon, in 69 cases by resection. Since that time Dr. Haggard of Nashville had reported additional cases, several being primarily unpublished cases from the Mayo Clinic. These cases followed two types: First, a lymphosarcoma which was infiltrating, and, second, a spindle cell or round cell or mixed form in which the tumors were large. As he understood, the tumor in Dr. Petersen's case weighed 410 grams, which was almost a pound. Lymphosarcomas, as a rule, were not bulky but infiltrating and ulcerating and caused no stenosis of the pylorus, a feature which was quite characteristic of this type of lymphosarcoma of the stomach.

Dr. ERDMAN stated that there was at the present time a case of lymphosarcoma of the stomach on Dr. Pool's service at the New York Hospital. A gastroenterostomy had been done and a tumor was found in the distal one-third of the stomach. As the man's condition was not good enough to make it advisable to proceed with the radical operation a preliminary gastroenterostomy was performed. The man had returned for the second operation, but his condition was such that it did not seem advisable to attempt to remove the tumor. A section taken from the tumor had been examined and pronounced lymphosarcoma. Dr. Beer had presented a case of tuberculosis of the stomach in connection with which several interesting points were brought out, and Dr. Symmers, in discussing the case, brought out the point that lymphosarcoma of the stomach sometimes remained localized for a long period of time; it might be two years before the lymphoid cells broke away from their localized position and were poured into the circulation, causing the blood pictures of lymphatic leucemia.

Diverticulum of the Esophagus.—Dr. PETERSEN presented this case, a man 67 years of age, who gave a history of having had difficulty in swallowing with regurgitation of food, over a period of about ten years. The regurgitated material sometimes showed undigested food eaten many hours before. Associated with his dysphagia there was a chronic cough with some expectoration. The *x*-ray and esophagoscopic examination showed the presence of a pharyngoesophageal diverticulum of medium size. At operation an incision was made from the level of the hyoid bone almost to the sternal notch, along the inner edge of the sterno mastoid muscle. The esophagus was exposed and the diverticulum located without difficulty. The sac was freed and cut away, great care being taken to prevent any leakage. The stump was cauterized and closed over with a suture of chromic catgut and the first suture line was then inverted with a second row of sutures. A small wick drain was placed in the lower end of the incision, after the closure of the neck incision. After operation nothing was given by mouth for three days. Fluids were administered by rectum during the time. The patient made a prompt recovery.

Dr. WILLIAM T. DORAN reported that he had seen a case of diverticulum of the esophagus in a new born child. The diagnosis made when the child was five days old was pyloric stenosis. Examination with the fluoroscope and catheter revealed a stenosis of the esophagus. A gastrostomy was done and it was found that the child had not only a stenosis but a diverticulum.

Dr. DE WITT STETTEN stated that he had operated upon only one case of diverticulum of the esophagus, some twelve years ago. At that time he studied the subject and went into the literature quite exhaustively. He said he wished to retract something he said in 1909. At that time he recommended a preliminary gastrostomy on account of the high mortality of direct excision of the sac, namely over 18 per cent. He felt now that with the improved technique of Judd, Bevan, and others, a preliminary gastrostomy might be dispensed with except in cases of severe inanition. His patient was still alive at the age of 76 years and was entirely free from esophageal symptoms.

Epithelial Papilloma of the Kidney.—Dr. CARL

EGGERS presented this patient, a man 59 years of age. His chief symptoms were hematuria, weakness, and dyspnea. He had had periodical attacks of hematuria for about a year. Pain was present only when clots formed and had to be expelled. The patient was operated upon on May 7, 1920, a nephrectomy being performed in the usual way. The kidney was about normal size. The tumor was in the pelvis of the kidney, upon opening which a soft villous tumor presented. The pathologist (Dr. Felsen) reported that it was an epithelial papilloma.

Horseshoe Kidney.—Dr. EGGERS also presented this patient, an ex-service man, 23 years of age. The symptoms first manifested themselves while he was overseas, the outstanding one being pain in the upper abdomen when he attempted to lift anything, followed by a desire to urinate. A laparotomy was done and the kidney found to extend from the normal position of the kidney on the right side across the median line to the left side with the concavity upwards. It was about two inches wide by one inch thick and lobulated. It was decided that nothing could be done and the wound was closed. A subsequent cystoscopy with injection of the pelves showed that the kidney had two distinct pelves, that showed no communication whatever.

Fracture of the Skull in Children: A Statistical Survey of 100 Cases.—Dr. JOHN J. MOORHEAD presented this contribution. He stated that this group of cases was from the surgical service of the Harlem Hospital and comprised 100 consecutive cases treated by four visiting surgeons or their associates or assistants. The primary object of the survey was to ascertain the surgical results with and without operation. The age limits in the group ranged from 3 months to 16 years, the average being 6½ years. Various writers stated that in vault injuries the mortality was from 10 to 20 per cent., in basal injuries 30 to 50 per cent., and in combined vault and base injuries from 30 to 60 per cent. The speaker's statistics showed that in vault cases the mortality was 5 per cent., in basal cases 10 per cent., and in vault and basal combinations 11 per cent.; in other words involvement of the base in any form meant a mortality of 80 per cent. of the total. In the 26 fatal cases in this series there were multiple injuries in 9. The combination of vault and basal fractures was very common in adults, about 80 per cent. radiating from vault to base and *vice versa*. In children this proportion was less, for anatomical reasons, and in the writer's series aggregated 32 per cent. From the clinical standpoint there were four main types of skull injuries, and these conformed to the adult grouping: Type I. (a) concussion plus vault fracture; (b) concussion plus base fracture; (c) concussion plus both vault and base fracture. Type II. Concussion plus latent interval plus focal symptoms (at first irritative and later paralytic) plus definite and indefinite signs of vault and base fracture. Type III. Concussion plus persisting coma plus definite signs of vault or basal fracture, or both, with convulsions, spasticities, high temperature, rapid pulse, embarrassed respiration, and exitus. Type IV. Concussion plus vault or base fracture, or both, plus evidence of intracerebral pressure. The differential diagnosis was not particularly difficult except in Types I. and IV., in which concussion and meningitis were respectively confusing. Concussion meant immediate temporary unconsciousness usually associated with vomiting. If the elements of immediate onset with temporary duration did not exist, then the condition was not true concussion. Confusion between head injury, with or without skull fracture, could be definitely determined in only three ways, namely, through inspection, as by incising a hematoma, by spinal tap, or by *x*-ray examination. Inasmuch as the differential diagnosis between hematoma and depressed fracture was especially puzzling in children, it was the part of wisdom to incise and actually see and feel. *X*-ray interpretation was harder in children than in adults, because the suture lines were more puzzling, because the thickness of the bones varied, and because children often moved when the plate was being made. In making a spinal tap, an even admixture of blood and spinal fluid was pathognomonic of skull injury, but an uneven mixture was very doubtful. Blood pressure and eye signs had not been found as valuable in children as in adults. Types I and II were the recoverable groups; type III was practically always fatal; type IV often ended in recovery if meningitis was not of a virulent grade. In the vast majority of fatal cases death occurred within the first 48 hours, and in cases ending fatally after that period death was usually from meningitis, pneumonia, an eruptive fever, or other more or less related intervening causes.

The routine management was of importance. Any suspected case should be kept absolutely quiet until all objective signs subsided. In a conscious patient bromides were given by mouth or rectally. Urotropin was administered every four hours for several days. Ten per cent. argyrol or 3½ per cent. watery solution of iodine was instilled into the nose and ears twice daily. The bowels were moved by enemata daily. If the diagnosis was in doubt the scalp was shaved, careful bimanual palpation was made for hematoma and other thickenings, and, if necessary, such areas were incised. A spinal tap was performed to exclude basal fracture when necessary. In suspected cases temperature, pulse, and respiration were recorded every half hour. In doubtful cases the blood pressure readings and eye symptoms should not be neglected. The one cardinal indication for operation was *pressure*, and this could arise only from bone, blood, serum, pus, or foreign bodies. The extent of the lesion rather than the site was the cardinal rule as to operative indications. Operation might be demanded as immediate, intermediate, or late, depending upon the intracerebral lesion rather than upon the extracerebral site of injury. Operation was not advised as a routine, for it was their experience that intracerebral pressure due to effused blood was best relieved by spinal tap. When, however, the bony envelope was distorted by depressed fracture and when the hemorrhage was in the main cortical, operation was the best procedure. In unconscious patients little if any anesthesia might be needed until the pressure was released. In this series of 100 cases 12 were operated upon, 9 for vault, and 3 for combined vault and base fractures; in the former group 1 died, in the latter 2 died. It was often unnecessary to remove more than a small segment of bone, but much care was necessary to ascertain definitely by finger pressure that no portion of the inner table was left within. Post operative paresis of an arm or leg, secondary signs of localized or generalized intracerebral pressure, facial paralysis and eye and ear defects were often recovered from. If secondary signs of localized and generalized intracerebral pressure did not subside spontaneously, a spinal tap should be performed. This procedure was almost specific for post-traumatic headache and for certain types of vertigo in which the auditory and visual mechanisms were uninvolved. Epilepsy might be looked upon as a rare end-result in children who had sustained skull fracture. The further the injury from the motor-cortical zone the less the probability of epilepsy. Psychoses, mental impairment, and like conditions, were very rare sequelæ in the absence of grossly destructive lesions. In children cranial defects were much more likely to spontaneously close over than in adults, and thus in children one could confidently expect that such defects would rarely require surgical repair.

Lethal Factors in Acute Ileus.—Dr. FREDERICK T. VAN BEUREN, JR., read this paper, in which he said that the two questions "Why do people die of acute intestinal obstruction?" and "What are the factors responsible for the appearance of the symptoms: complex of acute ileus and which of them are essentially fatal?" must be answered provisionally at least, if they were to seriously attempt any improvement in the present mortality rate. He defined acute intestinal obstruction as a local condition associated with the sudden abnormal stoppage—from any cause—of the intestinal current between the stomach and the anus. Acute ileus he defined as a general condition whose symptom-complex appeared when acute intestinal obstruction—from any cause—had existed long enough to make its effects manifest. The proper treatment for acute ileus, whatever its underlying cause, was similar in every case; while the appropriate treatment for intestinal obstruction varied according to its mechanical, spastic, or paralytic character. Whoever failed to appreciate the practical difference between obstruction and ileus might readily fail to recall that the latter deserved its

proper treatment quite as much as the former. And, again, if he failed to apply his knowledge of this fact he would lose cases of acute ileus that he ought to save. Acute intestinal obstruction bore to acute ileus, roughly, the same relation that a wound contamination bore to systemic infection. One was a local condition and an underlying cause of the other. After developing this conception somewhat further, Dr. van Beuren applied it to a series of cases of obstructed or strangulated hernia together with cases of intestinal obstruction from all other causes operated upon for acute ileus at the Roosevelt Hospital during the past ten years. He had included the cases of obstructed or strangulated hernia because he wished to emphasize his belief that, in the interest of better mortality statistics for strangulated hernia as well as for other mechanisms of the underlying cause of acute ileus, they should be included and to make the point that acute ileus resulting from strangulated hernia deserved treatment quite as much as acute ileus arising from the common postoperative mechanisms such as bands and adhesions. The point was that ileus, whatever its underlying cause, deserved prompt treatment. The facts were that in strangulated hernia ileus, the hernia was the prominent feature; it received prompt treatment and the ileus did not. In ileus that arose from other causes than external hernia, the ileus was the prominent feature and neither the ileus nor the underlying cause received prompt treatment. Evidence of this statement could be found in the mortality statistics of intestinal obstruction from almost any general hospital. The death rate varied from 30 to 60 per cent., and averaged between 40 and 50 per cent. Their operative statistics showed that the mortality was less than 20 per cent. where operation followed within twenty-four hours of the onset of symptoms; over 70 per cent. where it was delayed seventy-two hours. Only one-third of their cases in which the elapsed time could be satisfactorily calculated were operated upon within twenty-four hours after the onset of symptoms. Only 12 per cent. of these cases originated in the hospital; the remainder were mainly emergency operations. These average mortalities, however, did not apply to every individual case. Cases were cited showing marked individual variations. It was perfectly clear that there were individual variations in resistance that partly determined the outcome. Low resistance was the first factor in the high mortality of acute ileus. It was for the most part beyond the surgeon's control, but a serious effort should be made to estimate the individual's resistance in each case, and to plan or modify the treatment in accordance with this estimate. There were two other factors which, if allowed to go on acting, would in the end prevail over the stoutest efforts of the organism to adapt itself. They were (1) intestinal damage and (2) the formation of poisons within the intestine. After deducing some of the evidence as to the independence or preponderant effect of either, Dr. van Beuren stated that he believed where massive gross damage was done to the intestine, its blood vessels and nerves, another deadly factor was apparent (3) *shock*. He preferred to believe that shock from some cause other than the absorption of intestinal poison played a major part in the outcome of certain cases of acute ileus. This peculiar condition which had not been satisfactorily explained appeared relatively early in cases of obstruction where a portion of the intestine had had its mesenteric blood supply occluded by volvulus, mesenteric thrombosis or other mechanisms of strangulation. From observations in humans and in animals he felt fairly safe in saying that the more sudden the onset of the blood stasis and the larger the amount of intestine involved, the greater the accompanying shock. A fifth factor predisposing to the fatal outcome of acute ileus was dehydration, due to the output of water by urine, sweat, respiration and especially vomitus, which was greater than the intake. This was by no means the least of the predisposing lethal factors in acute ileus. Dr. van Beuren stated that having outlined the factors which, in the patient's body, must be estimated and allowed for in one's plan for treatment, it would be unfair to forget those factors which one should combat in his own mind before he could effectively translate his plan into action. Timidity and delay on the doctor's part were just as fatal factors in acute ileus as any that had been ascribed to the sick man's own economy.

The Treatment of Erysipelas with Chinosol and Sodium Chloride.—Dr. WILLIAM C. LUSK read this paper, which will be published in full in the *Annals of Surgery*. The chinosol preparations employed were an ointment and a tincture. *The Chinosol Ointment*: ℞ Aquæ dest. (cold sterile) ʒss, to which add, and dissolve in the same, pulv. chinosol grs. x, then add sodium chloride (reagent) grs. iv, and rub up, first with lanolin ʒss, finally incorporating vaseline (white) ʒss, M. et Sig.: Chinosol ointment. This ointment had other uses. Applied 5 times in the 24 hrs., to normal or inflamed skin of both adults and children, by smearing it on, in the treatment of the erysipelas cases, it had caused not the slightest observable irritation. In two cases, however, the ointment, running into the eyes, apparently was the cause of a vascular injection of the sclera, which rapidly cleared up with the application of boric acid compresses. An ointment containing 8 grains of chinosol to the ounce, without sodium chloride, had caused skin irritation. *The Tincture of Chinosol with Acetone and Sodium Chloride.* ℞ Aquæ dest. (10 parts) ʒiss, ♏xlviii, which boil and make cold in ice-box; then add and dissolve chinosol powder (2½ per cent.) grains cxcii; then add 95 per cent. alcohol (70 parts) ʒxi, ʒi, ♏xxxvi; shake and add acetone (20 parts) ʒiii, ʒi, ♏xxxvi; shake and add without delay, because otherwise a precipitate of chinosol will soon begin to form, sodium chloride (reagent) grains xcvi; shake vigorously 5 to 10 minutes. A flocculent precipitate will now form which soon redissolves. The insoluble residue is sodium chloride. Let stand over night and then strain through sterile cotton. Sig.: Tincture Chinosol with Acetone and Sodium Chloride. This tincture also had other uses. In making up the tincture of chinosol the glass receptacles and utensils used, should be scoured with neutral sodium oleate, and should then be boiled in plain water. An alkali would precipitate oxyquinolin from the chinosol (oxyquinolin sulphate), so that soda should not be put into the water used for boiling. Nor should the glass be treated with hydrochloric acid. A glass vessel was preferable as a container. Iron would discolor the chinosol. This tincture of chinosol applied freely to the skin three times a day and twice at night had never been observed to cause any irritation, either when used alone or when preceded by an ether wash, even on the skins of young children.

The Treatment.—The routine treatment consisted in the use of the chinosol ointment for all adult cases of facial erysipelas and for erysipelas affecting all parts of the body in children, and the use of the tincture of chinosol, preceded by a wash of the skin surface with ether, for all adult cases of erysipelas of the scalp, trunk and extremities. Treatments were administered three times during the day, at 4 hour intervals, and twice at night. Owing to the fact that bacteria had been found by the speaker in considerable abundance in the subcutaneous fat beneath the normal appearing skin one inch in advance of the line of demarcation of the erythema, the area treated included a belt of the normal appearing skin, 3 or 4 inches in width, adjoining the line of demarcation. In cases of facial erysipelas, eye lids which had not swelled, were always included in the anointed area from the start. The ointment was applied by gently smearing it over the skin surface, generally by means of a wooden tongue depressor. An excessive amount of ointment on the eye-lids should be wiped off with cotton. The tincture of chinosol was painted on the skin surface in several successive layers, as drying of each took place, with a large camel's hair brush devoid of metal, following gentle washing of the skin with cotton dripping-wet with ether.

The Results.—The cases were admitted to the erysipelas ward of Bellevue Hospital between Feb. 10 and March 25, 1921. The test of the efficiency of the treatment was sought in the control of the spread of the erysipelas and not in the control of the temperature. There was a total of 95 cases, which comprised 71 cases of adult erysipelas of the face and scalp, of which 24 (33.8 per cent.) had no spread of the disease after admission, and 14 (19.7 per cent.) had no more than one day of spreading; 8 cases of adult

erysipelas of the extremities, of which 4 (50 per cent.) had no spread after admission, and 3 (37.5 per cent.) had but one day of spreading; 8 cases of children's erysipelas of the face, of which 6 (75 per cent.) had no spread after admission, and 8 cases of children's erysipelas of the trunk and extremities, of which 1 case (12.5 per cent.) had no spread after admission, 1 case had out one day of spreading, 1 case recovered early, 1 case had two days of spreading, 1 case twelve days, and 3 cases died. Out of 12 cases of erysipelas involving the back, in 8 (6 adults and 2 children) the erysipelas soon became checked, in 1 (a baby) it spread unchecked, and 3 died (2 malnourished infants and 1 puny baby). The speaker ("The Disinfection of Vitalized Tissues and the Healing of Wounds with Chinosol and Salt," *Annals of Surgery*, 1919, pp. 493-497) had demonstrated the ability of certain solutions of chinosol and sodium chloride to cause the destruction of scientific infection in fresh experimental wounds.

Meckel's Diverticulum: Invagination, Intussusception, Perforation, Resection, Recovery.—Dr. JOSEPH E. J. KING presented this specimen. He stated that the patient from whom the specimen was removed was a German soldier, who came into the hospital about 7:30 p.m., January 21, 1917, with the symptoms of a typical acute appendicitis. He was operated on about 8:15 p.m. Several days after the operation, the patient stated that in November, 1916, he had been taken sick with acute pain in the right side of the abdomen (right iliac region). From November 15 until December 22 he was treated in a hospital with ice caps, etc., for "chronic appendicitis." He was transferred to a base hospital, where this treatment was continued. Later he was sent to a convalescent home. Finally he recovered, and was sent to a substitute battalion, for light duty. From his battalion he obtained a furlough, and while en route to his home he was suddenly taken ill with violent abdominal pain, more on the right lower side. He was taken from the train at Oppeln and sent to the hospital. He was a well-developed man, 26 years of age, walked into the hospital from ambulance with his luggage, arms, etc. He presented the typical signs of acute gangrenous appendicitis. The operation was done through a pararectus incision of the usual length. Search was made for the appendix and cecum. Both were found to be congested but apparently were not the cause of the trouble. There was a considerable amount of seropurulent fluid present. The incision was enlarged upward and downward. About twelve inches from the ileocecal junction there was found an abstruction of the ileum. The proximal portion was distended, the walls were thinned out; the distal portion was collapsed. Intervening was a mass on the inside of the lumen of the gut, its character could not be ascertained. Opposite the attachment of the mesentery, on the dilated proximal portion, the tip of the appendix was attached, firmly adherent, so that the appendix was hammocked across from the cecum to this dilated ileum. The point at which the appendix was adherent represented the location of the previous perforation of the ileum. Resection of the ileum, with a portion on either side of the obstruction, was done, followed by a lateral ileocolostomy. Cigarette drains were inserted. The patient made a recovery as after an ordinary subacute or a favorable acute case of appendicitis. The specimen showed about 12 inches of the resected ileum. When the lumen of the gut was opened it showed an inverted Meckel's diverticulum, about 2½ inches long, turned outside-in like a glove finger. This mass was carried down the intestine by peristalsis and produced a partial intussusception. The obstruction was almost complete; only a probe could be passed by the diverticulum. This obstruction was followed by dilatation and perforation of the ileum.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held March 22, 1921.

DR. CHARLES G. CHILD IN THE CHAIR.

Postoperative Tetany.—Dr. WILLIAM P. HEALY reported these cases. He stated that tetany should not be regarded as a disease conception but as "a more or less localized manifestation of a convulsive nature—due to a large number of exciting causes—possibly with some single and unique underlying factor." It was not a common clinical factor and was rarely seen in adults. The epidemic form had never been reported in the United States. The researches of MacCallum and Voegtlin had suggested the probaole value of the calcium salts in the treatment of the various forms of human tetany. The cases which Dr. Healy reported were instances of postoperative tetany in adults after celiotomy for operations on the pelvic viscera. There were seven cases. The onset of the typical hand symptoms was observed as early as seven hours after operation in one case. The symptoms terminated within forty-eight hours in each case either in response to treatment or by the death of the patient. There were four deaths and three recoveries, the latter after the administration of calcium lactate by mouth. In the fatal cases, despite thorough postmortem in two, with careful antemortem blood studies, no positive information as to the probable or exact cause of death was obtained. The symptoms in the fatal cases were tachycardia, profuse diaphoresis, hyperpyrexia, epigastric distress, bilateral symmetrical spasms and contractions of the muscles, especially of the upper extremity, and convulsions. The prompt recovery in the fifth, sixth, and seventh cases satisfied them that they were dealing with a form of toxic tetany of chemical origin. The source of trouble was apparently finally traced to the glucose and sodium bicarbonate administered as a routine to most of the major operation cases. This was supposed to contain 5 per cent glucose and 5 per cent sodium bicarbonate in 8 ounces of water at a temperature of 100° to 110° F. It was given as soon as possible after the return of the patient from the operating room, and was repeated again in four hours. Through an error in calculation 1,200 grains of sodium bicarbonate was given with each enema instead of 130 grains and enough of this was absorbed in a short time to upset the normal relations between the sodium, potassium, calcium, and other ions in the neuromuscular tissues—resulting in the symptoms described. After reviewing the work of Münser, Greenwald, and Binger as to the action of neutral solutions of sodium salts, Dr. Healy said that the question was whether the condition was one of alkalosis due to the administration of an excessive quantity of sodium bicarbonate or a condition of sodium poisoning in which the symptoms resulted from a disturbed balance of normal relations between sodium, potassium, calcium, and other ions. His own impression based upon the prompt response to treatment with calcium salts was that these were cases of sodium poisoning and not of alkalosis.

Dr. ISIDOR GREENWALD said it seemed to him that anyone who looked over the histories of these cases would agree that the administration of sodium bicarbonate was responsible for the tetany. It was merely a question of the mechanism by which it acted. Sodium bicarbonate acted in three ways: First, it was an alkali and might cause "alkalosis"; secondly, it was a salt and caused changes in osmotic pressure, and, thirdly, it would seem that it should produce a disturbance in the balance of sodium and calcium and other ions. In regard to the action of other sodium salts: sodium chloride produced a disturbance in which the neuromuscular symptoms were most conspicuous; with sodium phosphate these were much less marked. In giving sodium bicarbonate, one of the most common results was respiratory failure. Tetany might be absent. Changes in osmotic pressure probably had something to do with the symptoms observed after injecting hypertonic glucose solutions, but there seemed to him to be no question but that some of the symptoms were due to the disturbance in the balance between the calcium and sodium ions in the blood.

Papillary Cystadenoma of the Ovary.—Dr. HARRY VAN NESS SPAULDING read this paper written in collaboration with Dr. John F. Erdmann, the statistics and case histories being taken from the records of the Post-Graduate Hospital. He stated that papillary cystadenoma was the most important surgical disease of the ovary. In a review of 5,000 pathological sections in the pathological department of the Post-Graduate Medical School and Hospital, cystic disease of the ovary was found to constitute 200, or 4 per cent., and

of these 200, 36, or 18 per cent were papillary. A review of the observations of others showed that the frequency varied from 10 to 27.4 per cent of all ovaries. In addition, 13 of Dr. Erdman's private patients operated upon elsewhere than at the Post-Graduate Hospital and three of the writer's cases were incorporated. While the histogenesis of ovarian cysts was very confusing, the most probable development was from a cellular perversion of the germinal epithelium. A review of a series of papillary sections impressed one with two facts: (1) The very gradual transition, with no line of distinction from the benign to the malignant, and to the typically carcinomatous picture; and (2) that a simple, apparently benign papillary area might exist in the same section with a complex or malignant field, from which clinically one could only conclude that there was no clinical method whereby the degrees of malignancy could be determined except by the microscope. The last word was therefore that of the pathologist. Microscopical examination in the present series indicated that 23 per cent. were benign; 16.6 per cent. premalignant; and 50 per cent. malignant; 22.2 per cent. were bilateral and 13.8 per cent. multiocular. Therefore out of 200 cases of all types of ovarian tumors, 12 per cent. were malignant or premalignant papillomas. Other observers had shown a higher percentage of malignancy. Every warty or papillary intracystic deposit and every secondary cyst, however small, should be sectioned for malignancy. These tumors showed a strong tendency to bilateralism and general metastasis was not rare. Bilateralism, especially as related to the solid form of ovarian tumors, usually indicated a carcinomatous process elsewhere in the body. All bilateral ovarian tumors demanded a careful examination of the abdominal viscera and breasts. In papillary cystadenoma of the ovary there was no specific ovarian symptomatology. The subjective symptoms were in every case referable to other organs and the objective symptoms were vague, uncertain, and often absent. The symptoms were dependent largely upon the size of the tumor and whether or not rupture or pedicular torsion had occurred. The accumulation of fluid in the peritoneum and its accompanying symptoms were among the first signs noted by the patient. This was an advanced symptom and indicated rupture, peritoneal metastases, and often malignancy. Every woman with ascites without sufficient explanation in the liver, heart, peritoneum, or kidneys, should be laparotomized even though bimanual examination gave negative results. Papillary cysts were particularly prone to become cancerous, but clinically there was nothing to suggest malignancy for a long time. In the event of malignancy, however, both the size of the abdomen and the emaciation generally increased. Many cases showed marked cachexia and asthenia, and these cases were apparently malignant from the beginning. These growths rarely showed the rapid progress of neoplasms associated with other glandular or structural tissues. Of the series of cases at the Post-Graduate Hospital 66.6 per cent were malignant or potentially so. Certain conclusions with reference to prognosis could be drawn: When a cyst was removed intact without peritoneal contamination, it lost its prognostic interest, however malignant the pathologist might report it later. There was always that indeterminate personal equation which could not be solved by the prognosis in other cases; prognosis as to recurrence improved with the age of incidence; in a certain number of cases in which rupture had occurred and the peritoneum was abundantly studded with warts, ovariotomy had proven a sufficient therapeutic measure to cause a regression of the remaining irremovable peritoneal deposits. They felt that this was quite exceptional and while such patients might linger for a number of years, yet they would finally succumb to the toxic exhaustion of the malignant peritonitis. They considered papillary ovarian tumors potentially malignant and if ruptured they usually eventuated in malignancy. In adenocarcinoma recurrence was probable and mortality high. Every ovarian cyst must be removed intact by abdominal section as soon as discovered. If unilateral oophorectomy was performed the patient should be periodically examined. Careless or rough handling, resulting in intra-abdominal rupture, tapping to reduce the size of the tumor, and the vaginal approach could not be too strongly condemned. Radium should be employed in cases in which the ovaries or the peritoneal implants could not be surgically removed.

Dr. WILLIAM P. HEALY emphasized the point that sometimes one came across a case of this type of papillary cystadenoma in which the condition was apparently inoperable; a celiotomy was done and one reached the conclusion that it would be unwise to remove the mass or even a part of it, and the abdomen was closed. He had had such an experience some years ago and had had the patient remain under his observation. She had had a papillary cyst of the left ovary, filling the whole left side of the abdomen and apparently inoperable. After the operation the fluid accumulated much more slowly than before and a year later bimanual examination led him to believe that, while the tumor mass was much more extensive than at the time of the exploratory laparotomy, it was a type suggesting the possibility of removal. He then did an exploratory laparotomy and found it possible to remove the tumor. He did a complete hysterectomy, and the patient survived and had remained well. There remained, however, numerous small wart-like excrescences on the bowel and parietal peritoneum which subsequently regressed after the removal of the greater portion of the tumor mass. So it was well to bear in mind that papillary cyst adenocarcinoma was something a little different from what we were accustomed to understand as cancer.

Dr. CHARLES G. CHILD expressed the opinion that this paper was one which would have a tremendous influence on our knowledge of ovarian pathology in the future. Dr. Spaulding had brought out the point that the incision should be large enough to permit the removal of the tumor without any attempt at aspiration for the purpose of reducing its size. That was a most valuable point. It was a distinct mistake to tap a cyst before attempting to remove it through the incision. If there had already been a spontaneous rupture of one of these cysts one could be almost sure that it was a malignant papillary cystadenoma and that there was little use trying to remove it. In operating on a papillary cystadenoma, if one was going to be satisfied with removing a single ovary, the other ovary should be kept under observation and if it showed any signs of enlarging it should be at once removed.

Dr. LEROY BROUN expressed his appreciation of the amount of work that had been expended in the preparation of Dr. Spaulding's paper, and said he was interested in the Doctor's statement that one in five ovarian tumors was papillomatous; he thought the ratio was one to four or one to three. He was glad to be corrected. The importance of this subject was brought out by Kelly twenty-five years ago when he stated that all ovarian cysts should be regarded as malignant until proven otherwise, which could only be done by removal. Dr. Broun did not agree with Dr. Spaulding and Dr. Child as to the necessity of the large incision. A tumor could be aspirated without scattering transplants if one used a small needle and took proper precautions. At the Woman's Hospital, in the case of a good sized tumor that would necessitate an incision beyond the umbilicus in order to remove it intact, they made a liberal incision to the umbilicus and exposed the tumor. They then aspirated with a small needle fitted to the rapid aspirating exhaust. In doing this the cyst wall was caught up on each side of the needle as soon as it became sufficiently flaccid to get a grasp. The cyst wall was in this way steadily drawn out of the abdominal cavity as it became more flaccid, and the adhesions could be more easily separated, so that there was less risk of rupturing the thinner portions of the wall of the cyst and scattering its contents.

Dr. SPAULDING, in closing the discussion, said that he had the highest respect for Dr. Broun's opinion, nevertheless, he felt that there was no mechanical method of tapping an ovarian cyst, regardless of how carefully the technique was carried out, that was not accompanied by some leakage. With the use of a small needle it required a long time to evacuate a large cyst, and at times the cyst contents were so gelatinous that they would not readily pass through the needle; or the cyst might be multilocular and then several attempts had to be made to evacuate the various loculi.

Episiotomy in Primiparous Labors.—Dr. S. J. SCADRON presented this communication, in which he emphasized the importance of the proper management of the second stage of labor. In his experience, as well as in the service of the Jewish Maternity Hospital, lacerations of the lower birth canal occurred in about 45 per cent. of all primiparous labors, and in about 10 per cent. of multiparous births. Experience had taught him that a timely median incision in the raphe anterior to the sphincter would prevent the over-stretching or tearing of the urogenital structures and the bladder attachments. As the presenting part further descended the levator ani muscle, and to some extent the transverse perinei, were called upon to functionate, the head tried to escape from under the pubic arch and through the vulva orifice in a forward and upward direction. This action of the head normally displaced the muscular structures backward encircling the greatest circumference of the advancing head posteriorly. If the action of the muscles was interfered with by a prolonged second stage, rigid perineum, or large head, the perineum became glistening and markedly distended; the anus became dilated early. One could hardly appreciate that at this stage there was an impending tear of the perineal structures, and that an episiotomy was indicated. Sometimes one found that the posterior commissure began to tear before there was this marked bulging; this was evidenced by slight hemorrhage. A timely incision would save the perineum. After the incision was made the head could easily be expressed with gentle hand pressure from above. In breech extraction the perineum should be excised before the breech was delivered, thus rendering it easier to bring down an unexpected extended arm without lacerations, and easier to deliver the aftercoming head. The technique of median episiotomy was simple. The forefinger was placed in the vagina during a uterine contraction and the hymenal ring would be felt as a tense band. With a straight blunt-pointed scissors an incision was made in the midline severing the tissues of the urogenital septum. The incision should be made gradually, not in one sweep; it should extend from one to one and a half inches on the skin surface of the perineum. It might be extended, if necessary, by cutting slightly away from the anus; if still more room was required the incision might be extended vaginally away from the rectum. In lateral episiotomy the incision was made through the skin, subcutaneous, and adipose tissues; here too the cut must be long enough to permit the expulsion of the presenting part; the incision was gauged as the presenting part advanced with each pain. In the repair of episiotomy the writer preferred plain gut. The wound was closed by interrupted buried sutures and the margin of the skin brought together by a continuous suture of the same material. Primary union was the usual result and the patient experienced very little or no perineal pain. It had been his experience that with the median incision there was better union than with the lateral incision and practically no scar tissue. The lateral episiotomy should be performed in cases of persistent occipitoposterior positions, especially when attempts at rotation were made with forceps. The writer also preferred the lateral incision in cases of breech extraction in a primiparous patient with a well developed child.

Dr. FREDERICK C. HOLDEN said he was always glad to hear another paper on episiotomy, the idea being that the more papers we had on the subject the more likelihood that those still opposed to the operation might come over to the idea that there was something in it. He used it in about 90 per cent of his primiparous patients. The results were excellent though he did not think it always prevented cystocele. One frequent mistake was that it was not done soon enough. It should be done before too much stretching had occurred.

Dr. HERVEY C. WILLIAMSON said he did not see how a median episiotomy was going to prevent a cystocele, as it was not done as he understood it until the head was on the peritoneum, and if there was going to be a cystocele the damage had occurred before the episiotomy was performed. He asked if a median episiotomy was performed a second time, and, if so, whether it was successful. He said he had always preferred the lateral incision.

Dr. CHILD said that Dr. Scadron's paper gave very well the indications for episiotomy and except in certain minor details he agreed with him fully. He had practised episiotomy for many years, ever since he had studied in the Rotunda Hospital of Dublin, but he had always used the lateral incision. At this point in labor our main thought was to prevent a solution of continuity of the tissues between the vulva and the rectum, and yet with median episiotomy the very condition was produced that we wished to avoid. The median incision was also directly in the line of lochial discharges, and was especially liable to infection if the incision was closed with catgut. In operations about the vagina he always used silkworm gut. There should be a thorough inspection of the vagina between pains and as soon as one saw that the limit of stretching had been reached and that little tears were beginning to appear in the vagina or fourchette then was the time to make the cut, but only through one levator ani muscle. This did not separate the transverse fibers of the levator ani muscles as the median incision did.

Miscellany.

The Cocaine Traffic in Paris.—Courtois-Suffit and Giroux give some of the details of this industry. Paris is the center of the French trade in "coco," as it is familiarly called. The headquarters are in the Montmartre district where the drug is peddled in the cabarets and dance halls. In the Latin Quarter the youth take it out of bravado without a thought of the consequences. It is sometimes called "foolish powder." The habit is eminently social in character and its devotees of all kinds meet in a democratic fashion and take a pinch all around. All sorts of ruses to avoid detection prevail. A fine cat made its habitual resting place over a caché worth thousands of francs. A traveling musician with a mandolin visited bar after bar, drew a crowd by singing and then took the drug from his instrument and offered it for sale. American troops on leave who had obtained cocaine from the Germans immediately after the armistice hurried to Paris to peddle it without any idea of criminality. Aviators found excellent opportunities of this kind. Gangs of peddlers hastened with their supplies into Belgium, Switzerland, and Spain. Pharmacists and their errand boys alike took part in the traffic, the latter naturally on their own account. Documents were forged and falsified when necessary. The profit on the German drug when retailed in Paris was 2,500 per cent. in some cases. There was, of course, the usual falsification. The addict is often forced to become a peddler to get his or her own supplies.—*Gazette des Hôpitaux*, June 25, 1921, xciv, 50.

Moving Pictures of Psychoses.—At a session last autumn of the Zürich Cantonal Medical Society, Dr. Hans Maier brought up the subject of the great importance for psychiatry of cinema demonstrations of the behavior of insane patients (*Schweizerische medizinische Wochenschrift*, May 12, 1921, li, 19). For decades affective behavior has been studied by Zürich psychiatrists, who have specialized in mimetic and pantomimic manifestations. The yield here supplements that of the association tests of Bleuler and Jung and of study of the psychogalvanic reflex at the hands of Veraguth, etc. While in other clinics the stress has been laid on convulsive phenomena, paralyses, etc., in cinematographic representations, at Zürich there has been a special study since 1917 of mimetic and affective behavior. The first pictures were taken at a velocity of 16 individual images per second, which was later increased to 25. The desideratum is a speed of 60 to 80, but this would prove very expensive. The author showed in his exhibition, in connection with 16 patients, 268 meters of film with 13,400 individual images. The patients were subjected to the same psychic stimulation or irritation, as follows: A taste irritant, two smells—one pleasant and one disagreeable; a needle prick, and a noise. According to the psychosis of the individual patient, both quantitative and qualitative differences were seen. A careful study of the films makes it possible to measure and analyze the muscular anomalies with ease and accuracy.

Death of Porak.—This distinguished obstetrician died on May 27, 1921, and his funeral oration was delivered at the tomb by Doléris. He was born in Paris in 1845, and his youth was influenced by several possibilities, including law, literature, natural science and medicine. The latter finally won out, after he had taken his B.A. in 1866. He was a hospital externe during the period 1867-72, and an interne for the ensuing two years. He graduated in medicine in 1878 and his thesis on icterus neonatorum was honored by a silver medal. By 1880 he had decided to devote his activities to an obstetrical career and he became chief of clinic to Depaul, who in certain other respects seems to have been his ideal. At a very early period in his career he obtained charge of two important maternity services, which he retained during the active period of his life—one was head of the obstetrical department of La Pitié and the other chief of the Paris Maternity School. His life seems to have been largely that of a technician and he wrote many interesting and valuable papers, but his chief service was in the direction of puericulture. During the first decade of the present century he was abnormally active in the domain of infant conservation, the most vital of French problems today. Outside of technics he was distinguished for his knowledge of the abstract sciences and linguistics. His personal attainments brought him into contact with many celebrities and he appears to have had a genius for friendships which caused him to be very sorely missed by hundreds of admirers. Despite the fact that the deceased had reached the ripe old age of 76 years, his obituary notice suggests that he was cut off prematurely.—*La Presse Médicale.*

Protecting Oysters From Infection.—In the *Gazette des Hôpitaux* for May 10-12, 1921, xciv, 37, Courtois-Suffit and Bourgeois outline a campaign intended to prevent the sale of contaminated oysters and other shellfish. They begin by stating that the method known as stabulation or flushing the oysters with antiseptic solutions works only in the laboratory. This is a surprise, for in the United States it has been shown to be quite practicable to irrigate the live oyster with hypochlorite solutions. In place of this resource there is only the method of complete bacteriological control as practised in Holland. Here there is no attempt made to disinfect shellfish already contaminated, but only to supervise the sound oyster and his kin. Thus far there is no legislation to compel the French oysterman to keep his product clean, but the Minister of the Merchant Marine furnishes bacteriological control on request. The oysters and their beds are then examined and the proper recommendations made. Certificates of cleanliness are issued if desired. During the war the oysters of the Mediterranean litoral were known to be badly contaminated. Two methods were employed to correct the situation, viz., stabulation and removal of sound oysters to reserve beds. The authors state that neither method is trustworthy owing to failure to sterilize or to opportunity for reinfection. As a matter of fact, they did not prevent the development of many cases of oyster typhoid. In Holland the state has for some years had exclusive responsibility for the purity of the oysters, and as a result shellfish typhoid has completely disappeared. The authors, therefore, recommend the full Holland plan to the French Government.

MANAGEMENT OF BONE AND JOINT INJURIES.*

BY A. P. STONER, M.D., F.A.C.S.

DES MOINES, IOWA.

THE principles of the treatment of recent fractures has undergone but few changes as the result of our recent military experiences. Mobilization with extension when necessary, by means of external splints, still holds first place; indeed, many surgeons with the widest experience in the war, maintain that with few exceptions all fractures are better treated by this method than by any form of internal splinting. The Thomas leg and arm splint, practically unknown before the war, came into universal service as the best mechanism for transporting and for holding the fragments in their normal approximation and alignment during the healing process.

Most war fractures were compounded, and compound fractures do not tolerate foreign materials, not even tendon or gut. These fractures are always infected, and metals and other foreign materials, including the bone graft, will inhibit the healing process. Even after the most thorough débridement of the soft structures still their application is unsafe. In compound fractures with much comminuted bone, before removing any fragment, it must be clearly established that it is completely devoid of its blood supply. Even in the presence of much suppuration spiculæ of bone may retain their osteogenetic power provided part of the periosteum remains intact, and it will finally unite and aid in filling up important gaps between the fragments.

In fractures involving a joint, the position in which the limb is placed immediately after reduction has much to do with maintaining the fragments in position.

A fracture of the neck of the femur requires flexion and abduction of the limb with extension longitudinally and laterally. With the aid of the Thomas splint and accessories for extension, it is rarely necessary to resort to operative measures for fracture of the femur. If the fracture is in the lower third, the leg should be flexed upon the thigh and extension applied in direct line with femur by means of tongs inserted into the lower fragment; the points of the tongs should not be inserted into the cancellous tissue and only deep enough to avoid their slipping. The tongs may be utilized to advantage in fractures of the lower third of both bones of the leg. Autogenous bone grafts or the steel plate, however, are to be recommended for fracture of the tibia and fibula when difficulty is encountered in reduction or in maintaining the fragments in position.

The Jones extension arm splint and the Thomas leg splint are equally effective in the treatment of fracture of the shaft of the humerus. Either of these splints may be fashioned out of iron rod ¼ inch in diameter and fitted to each individual case by the surgeon. The joints of the splint may be brazed in any machine shop in a few minutes' time. When the injury is in the vicinity of the shoulder joint, or in the joint, the arm always should be secured in the abducted position. In such injuries, if the arm is permitted to rest against the chest wall until healing takes place, much difficulty may be experienced in getting it up into abduction, while on the other hand the arm will readily come down to its normal position as soon as the splint is removed, since there is no muscular rigidity to overcome, and gravitation lends a natural and constant aid to its resumption. Likewise, in fracture or other injuries of the ankle joint complete dorsal flexion of the foot should be maintained.

Care should be exercised that undue pressure is not made upon the axillary nerves by the shoulder ring of the Thomas or Jones splint. The autogenous bone peg steel plate or wire nail, however, when judiciously applied in fractures of the extreme upper or lower ends of the humerus, offers one of the best means for securing the fragments. Most fractures that involve the elbow joint are best treated with the forearm completely flexed upon the arm, Jones position.

In fractures of the lower end of the radius involving the wrist joint, it matters very little in what position the hand is placed relative to its position with the forearm, whether it be hyper-extended, straight or even flexed.

Complete reduction is the all-important thing in the treatment of Colles' fracture, so that the anatomic alignment of the fragments of the bone may be as nearly normal as possible; this, I believe, may be accomplished in all cases. In the majority of these accidents the lower fragment is literally driven into that of the upper. The force that breaks the bone is continued upward until the soft cancellous structure of the lower fragment becomes more or less completely embedded into the firmer structures of the shaft above.

Often it is impossible to dislodge the fragment by traction upon the hand, but it is easily unlocked by forcibly hyperextending the hand; then while the hand is still in this position, traction is made upon

*Read at seventeenth annual meeting American Association of Railway Surgeons, Chicago, October 6, 7, 8, 1920.

the hand, and the lower fragment is pressed downward as the hand is straightened out. This fragment is still further worked into place with the thumbs while traction in a straight line is continued upon the hand by an assistant. Once the reduction

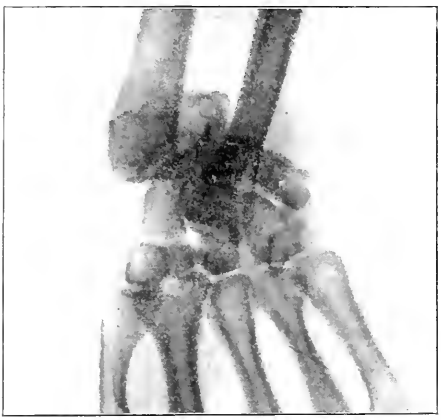

Fig. 1.—Case I, *a*. Fracture lower end of radius with complete dislocation of lower fragment backward and inward together with carpal bones. Caused by cranking an automobile. Anteroposterior view.

is completed it is not easily displaced. Now, however, begins a very important part of the treatment —that of reestablishing function of the wrist joint. Indeed, the setting of any bone is but one of the important steps in the procedure that requires weeks or months to re-establish normal function.

In the so-called Colles' fracture, if the hand and

arm be secured and kept in any one position without active or passive movements until the healing process is completed, the patient will be rewarded and the doctor chagrined by a more or less complete ankylosis of the wrist joint which may involve the elbow and shoulder in limited motion and much pain, especially if the arm is constantly carried in the proverbial sling. The fingers will remain stiffened by the inflammatory process of the tendon sheaths in the vicinity of the fracture.

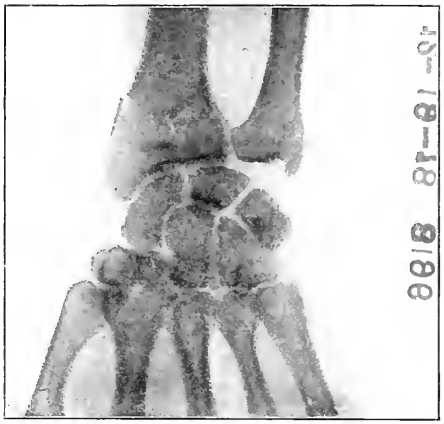

Fig. 3.—Case I, *c*. After reduction. Note the normal anatomical relations of the ulna and radius, and the nearly perfect alignment of the fragments of the fractured radius

For years I have used the circular plaster cast, converting it as soon as it has hardened into an antero-posterior splint for securing the fragments. However, this is a matter of personal choice and any well-padded splint may answer equally well. The fingers and thumb are to be left entirely free and active motion begun and continued as soon as the patient awakes from the anesthetic. On the

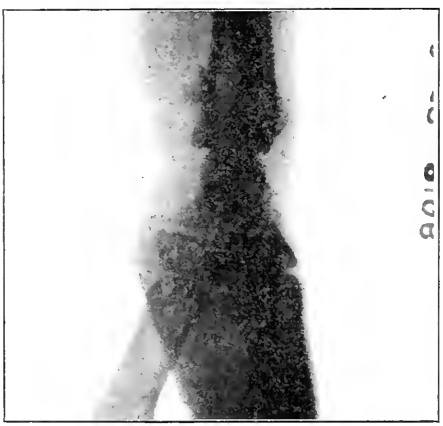

Fig. 4.—Case I, *d*. Lateral view after complete reduction. Note the normal angle of the articular surface of the lower end of radius in its relation to that of the carpal bones which form the wrist joint. Full range movement of the joint was re-established after second month.

second day the splints are taken off, the wrist joint is massaged and the hand may be slowly and carefully flexed and extended by the surgeon. These procedures are repeated daily or twice daily thereafter. The anterior splint is dispensed with on the

third day and the posterior splint is discarded in 10 days, after which time the patient is encouraged to flex and extend the hand by muscular action alone. Massage is continued until the function of the joint is restored. Unfortunately, owing to the

It would have been impractical without operative measures to dress the arm in a straight position, the fragments could not have been brought together into their normal anatomical relations.

danger of displacing the fragments, one is not at liberty to manipulate all joint fractures as one may handle the wrist joint after Colles' fracture. A very large percentage of fractures of the lower end of the radius really need no splinting, for once complete reduction is effected it requires consider-

able force to disturb the relations of the fragments.

So much has been written recently upon the subject of war injuries of bone and joints that one hesitates to undertake a rehearsal of or add anything to the voluminous literature now being compiled. The military aspect of this discussion deals with the writer's experience in the treatment of fractures and dislocations while serving in the U. S. Army Base Hospital at Ft. Riley, Kan., where all casualties were treated during the training

FIG. 7.—Case III. Simple fracture of surgical neck of humerus, woman of 70, from being struck by an auto. Note the spicula of bone completely detached, lying below the head. Note also the abnormal angle between the head and shaft at side of fracture.

period of soldiers at Camp Funston. In addition to this work, I was privileged, through the courtesies extended by the chiefs of the orthopedic service, Maj. M. H. Rogers of Harvard University and Maj. F. D. Dickson of the University of Pennsylvania, to observe and associate with them in the treatment of many other interesting joint and bone cases. Most of these cases as well as those under my immediate supervision during the latter months of service, were gunshot injuries incurred overseas from 4 to 6 months prior to admission to the hospital at Ft. Riley.

In some cases the soft structures were healed,

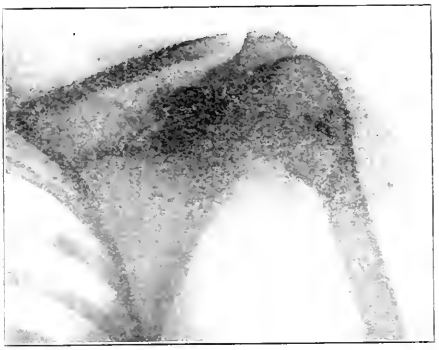

FIG. 8.—Case III. *b*. After four weeks' treatment with extension by means of a Thomas splint, the arm being kept at nearly right angle to the body. The spicula of bone has apparently united with the shaft. The anatomical alignment of the head and shaft is nearly normal. Normal movements of the shoulder resulted in six weeks' time.

other cases presented large areas of unhealed soft tissues, still others presented a sinus leading from the surface down to necrosed bone or cartilage. It should be the rule always to operate wherever there is a discharging sinus leading from the sur-

face down to the bone, regardless of a negative *x*-ray plate.

It goes without saying that all such cases in which evidence of bone disease is shown by the *x*-ray should be subjected to sequestrectomy. Every

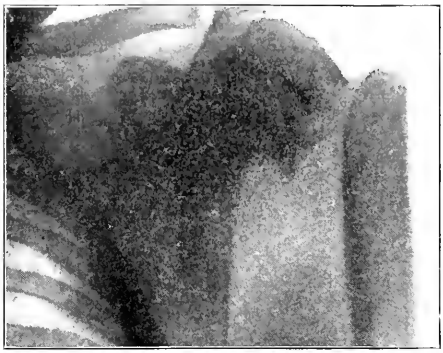

FIG. 9.—Case IV, *a*. Compound comminuted fracture, surgical neck of humerus. Caused by falling earth from a cave-in.

vestige of the diseased area of bone requires removal, relieving the bone of all pockets and gutters, by biting and chiseling away all overhanging edges of normal healthy bone cells. The bone curet alone is ineffectual for the removal of necrotic bone. More is required than that of merely scraping the bone. After sequestrectomy the wound should be immediately packed with Dakinized gauze and left in place 24 to 48 hours, after which the regular technique of chlorinization is instituted. This treatment renders what otherwise would be foul-smelling suppurating wound of the soft structures, a sweet and healthy healing surface without odor. Sloughing muscle and fascia melt away under its influence with surprising rapidity, while it effects no injury whatsoever to the living structures. Bacterial counts should be made at frequent intervals, and the wound may be closed when it becomes sterile. Experience has shown that a wound may be safely closed when the average is 1 organism in 5 fields in 5 or 6 successive counts. Such wounds never contain streptococcus or Welch bacillus.

It remains to be seen what the ultimate result of war-wrought bone necrosis will be. The poor resistance of bone to infective processes is well known. The general resistance of the soldier, however, was so much above the average civilian with osteomyelitis, the result of blood stream infection, that the prognosis in the former case should be more encouraging. It is well known that chronic osteomyelitis is a very intractable thing from whatever source it may spring and repeated operations often fail in eradicating the process, it certainly appears to be true in war infections of the bone.

The treatment of joint injuries remains one of the most unsettled questions of the principles and practice of surgery. The pendulum has swung back and forth between that of complete rest for certain periods and of immediate passive motion. It is only recently, however, that Willems of Ghent has demoralized all the staid surgical traditions in the treatment of infected joint injuries, and his principles are likewise applicable to simple joint injuries—by the immediate adoption of active motion. In infected knee joint injuries, for example, instead of rest, extension and drain, Willems has supplanted it by immediate active motion without extension after cleansing it and completely closing the joint. If pus forms in the joint it is reopened and the patient continues to flex and extend the leg at frequent intervals as before, and is made to walk while the joint is still open. These movements keep the joint emptied of pus and prevents ankylosis. The ankle joint is similarly treated. In elbow injuries the patient is made to flex and extend the forearm upon the arm as soon as he is awake after operation.

In practicing the restoration of function in joint injuries from fractures of opposing bones, account must be taken of the dangers of displacing fragments, and the proper course to pursue must often be left to the judgment of the surgeon in the individual case. Sir Robert Jones (*Surg., Gyn., and Obstet.*, January, 1920) recently formulated the following rules to be used as guides, namely:

That forcible movements are rarely indicated. If pain occurs after manipulation and is of short duration, movements may be continued. If pain occurs for lengthy period after manipulation rest is indicated. If the increased range of movement is maintained after manipulation, further movements may be safely prescribed. If in spite of movements, even in the absence of great pain, the range is continually diminishing, rest is indicated. The duration of pain when tissues are relaxed, rather than its intensity, should be our clinical guide. In overcoming adhesions and in subsequent manipulations, the joint should be put through its various movements only once. The oft-repeated pump handle movements applied at each sitting are never useful and often start inflammatory symptoms. Voluntary movements can safely be allowed and should be encouraged. They are not followed by obstructive reaction.

In some intractable cases with limited motion

FIG. 10.—Case IV, *b*. A bone peg was procured from the shaft of the tibia and driven at an obtuse angle into the head of the bone to aid in holding the fragments together. The broken end of the shaft was first sawn off square. The arm was dressed on an aeroplane splint at right angle to the body.

in which complete flexion and extension are impossible without eliciting great pain, I have found that after a few days of complete rest the patient is able fully to flex and extend the limb without pain. Dislocated joints after reduction should be put to

rest in plaster-of-paris for a few days when massage and slow passive motion should be practiced daily until function is restored. Hot fomentations or dry heat may be used to advantage.

By the aid of the *x*-ray any dislocation may be studied and the relations of the displaced bones so completely established that a novice should be able to effect their reduction. By this means one should obtain an accurate conception of the route through which the dislocated bone has passed, as well as the probable position assumed by the extremity during its excursion.

To return the parts to their normal position it is only necessary to reverse the route through which the articular surface passed during the accidents.

USE OF ROUND LIGAMENTS IN RETRODISPLACEMENT OF THE UTERUS.

By ASA W. COLLINS, M.D., F.A.C.S.,

San Francisco, Cal.

In order to understand the problem that confronts the surgeon when he undertakes to correct a malposition of the uterus, it is necessary to have clearly in mind what the normal position of the uterus should be, how it is maintained in its normal position, and also the mechanism of the process by which the uterus becomes reflexed, retroverted, or prolapsed.

Motility is one of the characteristics of the uterus, for it is in no sense a fixed organ. It is displaced backward when the bladder is distended, and slightly displaced forward when gas or feces are present in the rectum. The changes in intraabdominal pressure that occur at every respiration cause a corresponding change in the position of the uterus.

Physiology.—Passing to a consideration of the physiological arrangements that make it possible for the uterus to respond to all these changes of position and yet return to its normal place, mention should first be made of the broad ligaments. These ligaments serve as supports for the uterine appendages, and also conduct the blood vessels to the uterus. Moreover, they inclose muscular bands that, reaching from the sides of the pelvis to the uterus, limit the movements of the uterus from above downward, as well as from one side to the other. These ligaments are composed of bands of fibrous tissue, with an interlacing of smooth muscular fibers.

From the posterior surface of the uterus to the lateral parts of the sacrum we find the uterosacral ligaments which hold up the cervix in the hollow of the sacrum. When the body is held in an upright position, the muscular fibers of these ligaments tend to elevate the cervix rather than to retract it, so that they are, in a sense, the suspensory ligaments of the uterus. According to Stewart McKay, the muscle fibers that run in the uterosacral ligaments are more or less continuous, not only with the fibers of the uterus, but with the muscular fibers of the bladder about the region where the ureter enters. There are also muscular bundles running from the sides of the bladder, below where the ureter enters, to the vagina, and again from the vagina to the walls of the rectum. This intimate relation of the muscular fibers of the bladder and vagina certainly helps to give some support to each organ, but the sacrouterine ligaments receive most aid from the uteropelvic ligaments which run in the broad ligaments at either side of the uterus, forming a sort of sling from side to side.

The round ligaments do not help to hold up the uterus; their function is to control to a certain extent the excursions of the fundus. They hold the fundus forward in such a way that the upper part of the posterior surface of the organ receives the intraabdominal pressure. The fundus is displaced toward the sacrum, upward and toward the back when the bladder is distended; when the contents of the bladder are discharged the round ligaments draw the fundus forward again.

Thus it is seen that, while the broad ligaments have a lateral pull upon the fundus, so that they limit its motion from side to side, and the infundibulopelvic ligament aids in keeping it steady, the round ligaments serve only to regulate its excursions from the normal position. The ligaments that have the most important part in keeping the uterus in position are the uterosacral, for they elevate and suspend the cervix, thus maintaining the fundus in a forward position. From the lateral walls of the pelvis the superior and inferior uteropelvic ligaments suspend the uterus on either side.

Lastly, the decussation of the muscular bundles coming from the uterosacral ligaments and the uteropelvic ligaments with the fibers of the cervix, as well as those of the base of the bladder, form an elastic diaphragm around the roof of the vagina, which not only helps to keep that canal up in position, but also serves to form a floor upon which the bladder and uterus rest. Thus the uterus and vagina are kept in position by being suspended from above and supported from below.

The normal position of the uterus, therefore, is seen to depend upon the proper fixation of the ligaments that maintain it. Should they lose this fixation the result would be that after the bladder and rectum are evacuated the elastic elements of the folds of Douglas will not be exerted, and the vaginal portion will remain in the anterior part of the pelvis. When the bladder fills again, the body of the uterus is pushed back, and with the ever-continuous filling and evacuation of the bladder and rectum the uterus eventually gets into a position where the effect of the pressure of the abdominal contents is not so great on its posterior as on its anterior surface, and the fundus will remain where it has been forced into the hollow of the sacrum. Continued intraabdominal pressure will usually force the uterine body still further down until it becomes completely retroflexed.

Retrodisplacements.—The examination of a woman who has borne several children, and whose uterus has been in a retroflexed condition for some length of time, will usually show that the broad ligaments are thickened because of the presence of varicose veins, a frequent occurrence with uterine retrodisplacements. The uterus itself is usually not injured by the displacement. It is the resulting torsion of the ovarian vessels with the

varicose development in the upper portion of the broad ligaments, and often of the infundibulopelvic and ovarian ligaments, that produces chronic congestion of both ovaries by extension of the uterus itself. Simple retroversion often

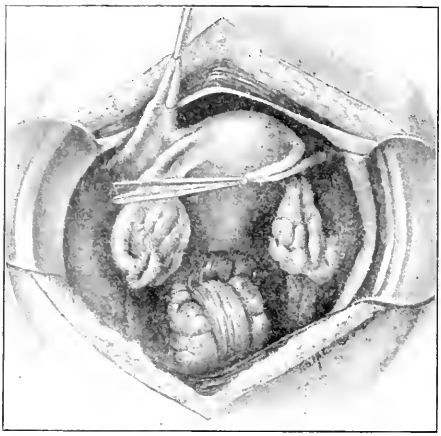

FIG. 1.—The forceps to the right shows the method of testing the point for beginning the denudation. Forceps to the left shows round ligament denuded, the peritoneum being incised and pressed backward.

produces no symptoms, but, as Pozzi[1] has declared, even if the displacement does not constitute a disease in itself, it renders the displaced organ very liable to attack from any source, as the circulatory changes produced by the increase in venous tension, which this position entails, tend to cause and increase inflammation both in the uterine cavity and upon the surface. Retroflexion is likewise often accompanied by a prolapse of the adnexa, and this in turn will give rise to distressing nervous symptoms, all of which are greatly enhanced when any inflammation takes place.

There have been many modes of operating for the relief of this condition of retroflexion, but we shall consider here only those that employ shortening of the round ligaments to accomplish that end.

A vaginal operation to shorten the round ligament has been devised by Wertheim, Byford, Bode, Ries, Vineberg, and Goffe. The underlying idea of all was to make an incision in the anterior fornix, through which a loop of round ligament was drawn. This loop was then fixed by pulling it toward the vaginal incision, where it was made fast by various devices.

The Alexander operation is typical of the "button-hole" method. This was performed in the year 1881 by both Alexander and Adams, although Alexander's account was not published until two years later. Kellogg[2] in 1888 performed the type of operation now most usually done. In 1916 he again published an account of his procedure, which he termed "blunt-hook dissection." A separate external incision is made for each ligament which is pulled through and attached by its thickest part to the aponeurosis of the external oblique at the upper angle of the puncture. This operation cannot be done upon fat women. Neither is it always successful with others, because in cases where the uterus has been retroflexed for a long time the fundus will have so increased in size that it will be below the place where the round ligament is attached. So, when traction is brought to bear by pulling the round ligaments instead of bringing up the fundus and straightening out the uterus, it will assume a still further position of retroflexion.

If the cases of retroflexion are complicated by ovarian and tubal difficulties or adhesions, an external operation, such as the Alexander,[3] will not suffice. The abdomen will have to be opened and intraabdominal shortening of the round ligaments performed. Gill Wylie folded the ligaments back upon themselves and united the folds, and Matthew Mann has also introduced a similar method. J. Clarence Webster[4] inserted a pair of forceps from behind through the broad ligament, grasped the round ligament and pulled it back and fastened it to the posterior face of the uterus. Baldy's[5] modification of this was to sever the round ligament, then with forceps to seize the proximal end of the distal portion which he fastened behind the uterus.

Ferguson and Gilliam drew the ligaments through perforations made on both sides of a median incision in the rectus muscle.

Stewart McKay[6] thus sums up the scope of the operations that may be performed on the round ligaments for the treatment of displacements of the uterus: The Alexander is an ideal operation for uncomplicated cases of retroversion and retroflexion, also for retroflexion complicated by adhesions, provided always that the adhesions can be broken down through the internal ring. It is useful in dealing with prolapsus in its early

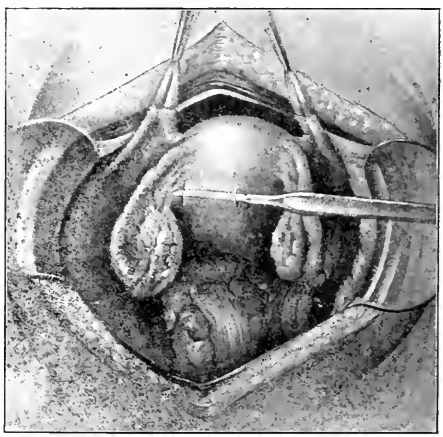

FIG. 2.—Both ligaments show the peritoneum retracted and the knife making the puncture.

stages, but it is valueless if the prolapsus is advanced. Intraabdominal shortening of the round ligaments is an efficient means of correcting and overcoming retroflexion of the uterus, although it has no effect on prolapsus.

Carey Culbertson[7] of Chicago employs the Webster technique in round ligament shortening, but believes that its use should be limited to a uterus that is relatively normal in size, free from pathology, and still in the years of child-bearing activity. It is not to be recommended when the outer parts of the round ligaments are noticeably thin, nor when the uterus is unusually heavy, as in marked subinvolution, extreme fibrosis, or chronic endometritis. Neither should it be employed in a uterus that contains fibroids or other neoplastic growths. Its use should be limited to cases where subsequent pregnancies are anticipated and where the tissues involved indicate its feasibility.

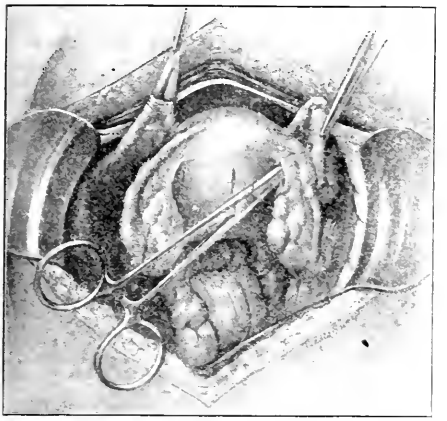

FIG. 3.—The ligaments are drawn under the Fallopian tubes and ovarian ligaments by forceps as shown in the illustration, or by a chromic ligature around the ligaments.

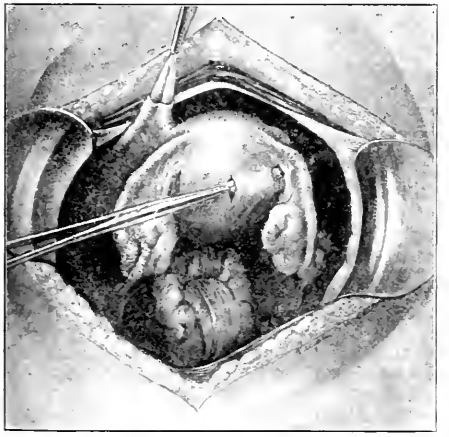

FIG. 4.—Each ligament is pulled through the stab wound in the uterus and sutured together by two chromic sutures.

Author's Operation.—In March, 1916,[8] I published an article describing an operation that I had been performing for two years, and since that time I have had opportunity to follow up many of the cases. The method employed is as follows: The uterus is held in normal position, the round ligaments are caught with Kelly forceps and brought toward the median line until the forceps meet behind the fundus, where the ligaments will eventually be sutured. At the point where the forceps has grasped the ligament, a circular incision is made around the ligament, cutting through the peritoneum. The forceps now grasps the denuded muscle of the round ligament and the peritoneum is peeled back for about an inch from either side of the forceps. With a thin-bladed knife a vertical incision about one-half inch long is made in the median line of the fundus posteriorly about opposite the uterine attachment of the ovarian ligament. From this point the knife is made to pass horizontally underneath the peritoneum and a short distance in the muscle and emerge close to the broad ligament. The same procedure is carried out on the opposite side. The denuded portion of the ligament is now drawn through the broad ligament underneath the tube and ovarian ligament, and another forceps placed through the uterine stab wound will draw the ligament to the median line. The same procedure is carried out on the opposite side. The two ligaments meeting in the median incision of the uterus are held together by suturing them with two chromic catgut sutures. Another chromic suture is placed from the uterus through the ligament at the site of the lateral incisions in the uterus and the operation is completed by closing the three incisions with plain catgut interrupted sutures.

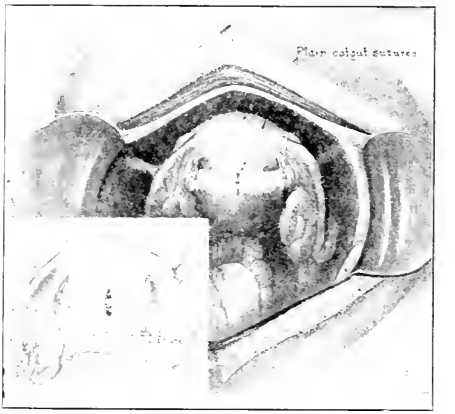

FIG. 5.—Insert shows ligaments sutured together with chromic catgut. The three incisions are closed by one plain catgut suture.

Comment.—A round ligament operation will hold a badly prolapsed uterus in position if the pelvic floor is properly repaired and the pelvic organs given their normal support, and no part of the pelvic anatomy will hold the uterus forward better than the round ligaments.

Round ligament operations have been unsuccessful for the following reasons: Too much reliance has been placed upon them as a means of supporting the weight of the uterus and adnexa; all previous operations have been peritoneal

attachments, which give way and cause the uterus to fall back or be drawn to either side; the Gilliam operaton has caused intestinal obstruction, is a suspension operation, and the Alexander operation can be used only in uncomplicated cases, which are very rare.

In conclusion, I wish to state that the operation herein described has met the test of time. It is safe. There are no raw edges, no adhesions to follow, and it permits the round ligaments to serve the uterus to the best possible advantage.

Conclusions.—1. It is a muscle-to-muscle attachment with no possibility of pulling away to one side or the other. 2. It is not a peritoneal attachment which forms an adhesion and will stretch or give away altogether. 3. There is no interference with pregnancy. 4. The uterus remains mobile. 5. No bladder nor other subjective symptoms follow. 6. It supports the ovary and relieves the varicosity of the veins of the broad ligament.

126 POST STREET

AN UNUSUAL PITUITARY CASE.

BY WILLIAM N. BERKELEY, A.B., B.Ph., M.D.,
NEW YORK,
ATTENDING INTERNIST, GOOD SAMARITAN DISPENSARY.

F. S., now 18 years old, female, single, living in Brooklyn, American-born, of Jewish parents, stenographer, first came to my clinic nine years ago. Her mother brought her for some intercurrent medical complaint which required no special treatment, and she was well in two or three days. Family history negative except as noted below. Stature normal.

Noting that she "blinked" continually, we referred her to Dr. C. B. Broder, of our Eye Department. Dr. Broder made the diagnosis of interstitial keratitis, and for this she was treated for some time, improving slowly. Her Wassermann was negative.

Two years later her mother brought her to me again. She had grown, and was a good-sized girl for eleven years,—well grown,—nothing more. She now had certain symptoms of renal disease. Her urine was examined at once, and showed abundant albumin, red blood cells, and epithelial casts,—also a marked positive reaction for glucose. We could never get a good 24 hours' specimen, but casual samples tested as high as 2 per cent. sugar. Inquiry showed that her mother and two of her mother's sisters had or had had diabetes. (One of the latter had since died at about 42 years of age, of diabetic gangrene).

Neither the patient nor her mother could be convinced of the gravity of the girl's condition. Ambulatory treatment failed entirely from lack of cooperation on the family's part. I therefore presently referred the girl to Mt. Sinai Hospital. Here she stayed some weeks, but later returned to us, still running albumin and glucose as before. Yet all this time her general condition seemed good; her blood pressure was low, and her physical examination negative.

She now disappeared again from observation, and two years later reappeared,—thirteen years old. She said she had had no treatment, and had eaten what she wanted. Her urine was now normal as far as we could determine—no albumin, no glucose.

Profile radiogram of skull, showing the large anterior and posterior clinoids (indicated by arrows) encroaching on the sella turcica.

She had grown and fattened, had a bright color (her own!), well developed breasts, and all external signs of puberty, though she was said not yet to have menstruated.

Three years later she again came about some intercurrent trouble. She appeared to be in perfect health; no albumin, no sugar. Blood glucose carefully determined at this time showed 0.110 per cent. (two hours after breakfast). She asked for a letter that she might be admitted to the list of "Farmerettes" for that summer (the European war was in full blast). She said she still had not menstruated.

After dropping from sight for two years more her mother brought her in January of this year (1921), desiring treatment for the persistent amenorrhea.

At this time her weight was 149 pounds (clothes on); her height, five feet, three inches in stockings.

Her blood pressure was 112 systolic (mercury manometer); color a little pale; intelligence fully normal. She had no headache; her visual fields were reported from the Eye Department to be unrestricted; her urine was entirely negative. She was working every day.

Wishing to find out something of her pituitary function, we had our radiographer, Miss Stich, make profile films of her skull. A print of one of these is shown herewith. Dr. J. M. Steiner, of New York, has kindly described the condition for me as follows:

"*Sella Turcica.*—Both the anteroposterior and perpendicular diameters of the sella are materially reduced in size. This is due very largely to the excessive size of both the anterior and posterior clinoid processes. Both the anterior and posterior clinoid processes are unusually large in width, and the posterior clinoid processes incline sharply forward and I believe are adherent to the anterior clinoid processes. The floor of the sella is smooth and rounded and without evidence of erosion or destruction.

"*Bones of the Cranial Vault.*—Both the inner and outer plates are a trifle thicker than one would expect to see in the average adolescent of eighteen years, and I believe that there is an unusually large amount of lime-salt deposits in the bones for a person of this patient's age. There is a complete closure and ossification of the sutures, and there is no evidence of erosion or destruction of the bones of the cranial vault.

"*Diagnosis.*—The plate creates an impression of overgrowth, excessive lime deposit, and extremely large accessory nasal sinuses, even the mastoids being distributed over a wide area, and I believe that this whole picture might readily be the result of what appears an anomalous condition of the sella turcica and possibly its bony pressure on the pituitary gland."

The condition suggested simple hypopituitarism as a provisional diagnosis, and therapeutically I did not think the case hopeless. I prescribed thyroid gland, to be followed a few weeks later by thyroid and whole pituitary combined, as soon as I should have determined the tolerance of the patient for thyroid alone.

Again, however, she failed to come back. When we last heard of her, she had stopped her medicine;—— "She would lose her job if she came during business hours," she reported. Her condition was said to be unchanged.

210 East Sixtieth Street.

TWO INSTANCES OF INVETERATE EPITHELIOMA FORMATION.

By Douglass W. Montgomery, M.D.,

and

George D. Culver, M.D.,

San Francisco, Cal.

As is well known epithelioma of the skin appears most frequently on the face, and is a disease of middle and advanced life, and occurs more frequently in men than in women. People vary in their susceptibility to developing these growths, but the following are instances of extreme propensity for such development.

On April 26, 1911, a man in excellent health, and thirty-five years of age, consulted us on account of a little fingernail-sized epithelioma in the hollow of the shell of the left ear. It had appeared like a blackhead one year previously. The lesion had a

Fig. 1.—Case of inveterate epithelioma formation. The figures represent situations in which seborrheic patches had degenerated into epitheliomata. The adhesive tape strips represent gold plaques in place.

well marked, characteristic, waxy border, and was quite hard.

We curetted it out and burnt the base with chromic acid. After the removal of the crust we x-rayed the surface. The healing was perfect, and there has been no return in this particular locality. Since then, however, he repeatedly has had epitheliomas in different situations on the face.

Fig. 2.—Same patient as shown in Fig. 1. The lower lip can be seen to be deformed. This is due to the action of the escharotical paste employed when he first consulted us.

For example, on October 13, 1911, he came in with a pea-sized nodular growth on the left cheek near the nose. This had begun as a small papule about one month previously. It was firm, had a raised rolled border and a rough fissured center,

and was surrounded by a narrow red areola. At times it was itchy. We treated this as we had the previous one with curetting, chromic acid and *x*-rays.

In the spring of the year following he came in with a flat wart of the forehead, and in the early part of 1913 he consulted us on account of epithelioma 0.25 cm. in diameter under the left nostril. This we curetted and burnt with trichloracetic acid. During the following summer a small crusted papule appeared over the left zygoma, which we treated in a similar way. In November, 1914, he arrived with a small epithelioma of the outer surface of the left tragus. This was curetted and found to be much deeper than at first anticipated. In fact, it buttonholed the skin. Here it may be remarked that epithelioma of the ear shell often shows itself as being particularly malignant, and in this patient the two worst epitheliomas were in this situation. This one we curetted and burnt out with chromic acid. In June, 1915, he again consulted us on account of a flattened, epitheliomatous disk about two millimeters in diameter on the nose. This was curetted and touched with trichloracetic acid. On October 23, 1915, an epithelioma had developed below the right corner of the mouth, which, on being curetted, left a deep, narrow cavity, which was burnt out with acid nitrate of mercury. On August 18, 1917, another epithelioma appeared over the right cheek bone. This was treated with radium. Another epithelioma appeared January 2, 1919, another on March 22, 1920, on the left side of the neck, another on the right side of the nose on August 12, 1920, another on the left cheek on March 9, 1921, and another April 30, 1921, on the left cheek.

As mentioned above, all these later epitheliomas have been treated with radium.

All the epitheliomas with the exception of the one in the left ear shell and one on the tragus of the ear were very small affairs.

The patient has a dull, oily complexion with very patulous sebaceous gland openings, and his skin is always unusually full of blood. The complexion is dark rather than fair. This is mentioned particularly, because people having a very fair skin are more subject to a multiplicity of epitheliomas than those with a dark complexion.

As the patient had a fatty skin, it was only natural to inquire into his fat intake. At one time he was taking more than sufficient butter and cream, but a diminution of this together with a lessening of his carbohydrates brought no noticeable amelioration.

As the actinic rays of sunlight are now known to be among the chief exciting causes of epithelioma of the exposed surfaces, and as the patient leads an outdoor life in the San Joaquin Valley where the sunlight in summer is intense, and the bright days are continuous, he was advised to wear a broad brimmed hat, lined with yellow or red, to absorb the noxious rays. These precautions, however, brought no noticeable relief. The greatest advance we made in the cure of this patient lay in the substitution of radium for the curet, cautery, and *x*-rays. The curet and cautery would ultimately lead to extensive scarring, and the frequent use of *x*-rays might finally cause senile changes, which are particularly to be avoided where cancer is concerned. The employment of radium is not attended by either of these defects.

Not long since a radium expert, who handles large quantities of radium commercially, exhibited his fingers, which were scarred with radium burns. He, however, had no fear of epithelioma developing from these radiations, as from *x*-ray burns. In other words, the action on the skin of *x*-rays and of the radiations from radium are similar, but by no means identical. This is especially true when the radium is heavily screened, so that only the finest wave lengths are employed.

The following is another instance of inveterate epithelioma formation:

In 1905, a farmer, thirty-eight years of age, called on us on account of an epithelioma below the left corner of the mouth. It was a rapidly growing lesion, and was both wide and deep. At that time we were employing arsenic, and the reaction from its application in his case was severe, and extended clear through into the mouth. On healing it left a permanent deformity.

Although he was a young man he had a great number of senile keratoses scattered over his face, some of which had degenerated into epitheliomata. The patient had a dry, irritable skin, and a fair complexion, such as burns but does not tan in the sun.

In a fatty organ such as the skin the history of any unusual intake of fat is interesting. This man for years used to come in from working in the field, at about 11 in the forenoon, and tip the top milk, almost pure cream, of a large pan into his stomach.

In the latter part of 1915 he was kicked by a horse in the left cheek, which left a wound which did not heal, and which developed into a large epitheliomatous ulcer, for which he consulted us in July, 1916. This was an interesting instance of a traumatism evoluting into a malignant growth. No lymphatic involvement developed from this, and a Wassermann reaction then taken was found negative. This ulcer was curetted and burnt out with chromic acid, and after separation of the crust it was treated with *x*-rays, under which it healed.

In the early part of this year (1921) he again consulted us. His face was mottled with keratoses, some of which had developed into rodent ulcers, and one into a coin-sized, fungating epithelioma. These were all treated with radium, heavily screened and retained in place for hours—the screening and time being varied according to the lesion.

This man's skin is quite different from that of the former patient, who has a dark, heavy, oily skin and a dark complexion, as contrasted with a fine textured skin and a light complexion. Yet both are subject in about an equal degree to the development of epithelioma.

As we look back over the histories of these two cases the first great advance in treatment was made by the employment of the *x*-rays, and the next still greater advance, by the introduction of radium.

The Excellencies of Radium.—Year after year radium continues to give off the same quantity of radiations; nothing retards it, nothing accelerates it, so that an operator having once become ac-

quainted with a radium plaque or tube, that factor for him is fixed. This holds as against an *x*-ray tube, which is very variable, and also as against radium emanation, which quickly deteriorates.

Another admirable feature is that being heavily screened it may be held in place for many hours, always exerting its influence. The advantage of this may be appreciated if one considers the nature of cancer, and the multiplication of cells in a growing tumor.

A tumor grows by cell division. The nucleus becomes active and the nuclear membrane disappears and the whole cell contents become scrambled together within the cell. Then two new nuclei form, the cell divides between them, and so two new cells come into being. It is probable that during the time that the nuclear membrane is absent, and what were the nuclear elements lie unprotected, the cell is particularly vulnerable. And as in a growing tumor the transformations are going on all the time, a prolonged exposure to gamma rays would catch crop after crop of these young cells. It would amount to the same thing as a prolonged sterilization. Even short interruptions, as exposures on successive days, would be equivalent to fractional sterilization.

The advantages of radium, therefore, in the treatment of these lesions are due to a number of physical peculiarities, as for instance, the steadiness and invariability of its action, its ease of application, and the length of time, running into hours, that it may be applied.

IMMUNITY IN TUBERCULOSIS.

By OWEN PAGET, M.D.,

PERTH, WEST AUSTRALIA.

To those whose range of vision is limited by the microscope the test-tube and the autoclave, the study of immunity in tuberculosis must be as difficult as "Paley's Evidences of Christianity" or "Esoteric Buddhism" to the Australian Aboriginal.

But progress, however slow, is ever taking place, and the study of nature, clinical teaching, and observation, together with such excellent text-books on the nose and throat, as that of Professor Ballinger, enable us to grasp not merely the theoretical conception of such a proposition, but that in reality it is an everyday circumstance, and physiological not pathological in quality.

"Currente Calamo," the celebrated French anatomist Professor Testut thus described the sense of smell: "Les appareils nerveux terminaux destinés à recueiller les sensations odorantes, sont disséminés chez l'homme, comme chez tous les mammifères, sur les parois de deux cavités appelées fosses nasales. Ces cavités sont creusées, de chaque côté de la ligne médiane, dans le massif osseux de la face, au-dessus de la cavité buccale qui renferme l'organe du gôut, au-dessous de l'orbite où se loge l'appareil de la vision. Elles occupent, comme on le voit, la portion la plus élevée *du long conduit que parcourt la colonne d'air de la respiration, s'ouvant en avant en pleine atmosphère et débouchant en arrière dans le pharynx.*

On consulting Professor Ballinger's text book on the Nose and Throat, it is obvious that he too regards the nose as an organ of, or at least a passage for respiration. He further points out that the inspiratory current passes into the upper area of the nose, above the level of the edge of the middle turbinate. This is a matter of the utmost importance. In some animals it appears as if there was a bony ridge separating the inspiratory and superior current from the expiratory and inferior current.

One further point must be taken into account, and that is the relationship in size between the nose and the other structures in the skull.

An *x*-ray photograph of a hyena's skull shows that the nose, irrespective of soft parts, is equal to the combined capacity of mouth and brain. Some African deer show an even larger proportion, and even in man the area allotted to the nose and sinuses is very considerable. Having established the fact that the nose is an organ of respiration as well as of smell, and having further indicated that it must from the large area it occupies in such an important structure as the skull, be an organ of importance, it is worthy of attention to establish the relationship between these functions, and the possibility of the existence of others.

Except the necessity for the inspiratory current of air, to pass into the upper chambers of the nose in order that we may smell, the actual sense of smell as judged by the area allotted to it in the nose is apparently of secondary importance. Even in the lower animals, whose requirements in this direction are more obligatory, the olfactory nerve distribution is mostly confined to the septum nasi in the region contiguous to the superior turbinate. It appears from this therefore that the various structures in the nose, such as the turbinate bones, the ciliated epithelium, and the nasal sinuses, must have some respiratory purpose, or functions hitherto undiscovered. Under conditions of nature, the most obvious impurity in the air, we breathe, is dust. Whether on the plains of Australia or on the prairie land of Canada, dust is an accompaniment of the movement of animals, or the occurrence of winds. On examining men exposed to dust conditions of a severe character, as occurs in some branches of the gold-mining industry, it is found, that men who breathe through their noses, and this compulsorily with a handkerchief over the mouth, do not develop miner's disease or tuberculosis. Further, in such cases the particles of dust are caught by the hairs at the entrance of the nostril or are deposited only on that part of the septum in front of the anterior ends of the inferior and middle turbinates. Thus dust of the ordinary quality "per se" cannot pass beyond the anterior cartilaginous part of the nose.

But even artificial dust of such a buoyant character as tobacco snuff acts apparently in a similar manner. For snuff makers, I am creditably informed, work with a handkerchief over the mouth and not over the nose. From the foregoing, it is apparent that *the nose is the filter of the lungs.*

Initiated by the researches of Pasteur, science and the world in general have become aware that the chief dangers to our existence are minute organisms invisible to the naked eye. The further investigations of Koch proved that the causative

agent of the most maiming and incidentally highly destructive infection known to mankind was the tubercle bacillus.

Faced with the proposition that the nose contained various structures of unknown utility, and that the inspiratory air contains numerous organisms known to be harmful, interest is at once aroused as to the happenings when these two factors come into contact. And this the more so, since we are already clinically aware that the tubercle bacillus is peculiarly virulent in its action towards the pulmonary tissues.

At once the extraordinary phenomenon arises that although the inspiratory air passes, except in mouth breathing, first of all over the nasal structures, nevertheless clinical nasal tuberculosis is of infinite rarity, whereas 80 per cent. of mankind show definite tuberculosis lesions of the lungs post mortem. Surely a subject for wonder. At least it shows that the nasal epithelial cells have a different capacity from those lining the pulmonary structures. On consulting Professor Skillern's text book on the Accessory Sinuses of the nose, I find the statement that the cells of the nasal mucosa have been shown to possess special bactericidal properties.

At this point the study of the circulation of the air in the nose attracts attention. If a manometer tube is taken closed at its outer end and securely fastened into the side of a cylinder of cardboard, a working model of nose and sinuses is produced. When breathing through this cardboard cylinder, if the distal orifice is the same diameter as the rest of the tube, there is no movement in the manometer with inspiration. The more, however, the distal orifice is closed the greater is the movement in the manometer with inspiration. Finally with too great a closure respiration becomes too difficult and ceases.

In normal nasal respiration, the commencement of inspiration draws the air from the nasopharynx, which causes the air to flow out of the sinuses. This flow continues till the end of inspiration, leaving a partial vacuum in the sinuses. When expiration begins, the last of the inspired air containing oxygen, and occupying the space above the soft palate is drawn by negative pressure into the sinuses, and it is there held until the next inspiration. Examination of the skulls of lower animals with their infinitely complex turbinate and ethmoidal structures shows that it is next to impossible for the inspired air to pass through this region without coming intimately into contact with their structures. The study of the circulation of the air in the sinuses has shown us there, too, the intimate contract which must take place between the inspired air and the lining cells. Since these lining cells are not only ciliated but constantly moist, the inspired microorganisms must with absolute certainty be deposited on them and digested or otherwise destroyed.

On theoretical grounds therefore it is impossible for a nose breather to be infected with tuberculosis, since no microorganisms can pass this ingenious filter, if it is in proper working order. Further experiment shows that the capacities of the nasal epithelial cells are not limited to their bactericidal action.

If in a case of tuberculosis, insufflations of suitable dosage of bacillary emulsion of tubercle bacilli are made into the ethmoidal region, certain and constant improvement takes place. This definitely shows that these epithelial cells which line the mucosa in the upper regions of the nose are capable of forming antibodies. *Hence immunity in tuberculosis resolves itself down to the establishment of a proper inspiratory current through the upper regions of the nose.*

With the present day excellent text-books on diseases of the nose, I feel considerable diffidence in making suggstions in this direction. In fact it seems best to depict outlines only. Pure mouth breathers, as children with adenoids, are beyond the range of the present proposition, because obviously they make no use of their nasal functions. But of special interest are those persons, who are partial nose breathers, and yet suffer from postnasal pharyngeal catarrh, different degrees of ethmoiditis, and more often than not some fairly definite pulmonary lesion, with a marked tendency toward fibrosis.

Now I have treated considerable numbers of these cases with insufflations of tubercle bacillary emulsion, and with very good results. But in a certain quite definite percentage the improvement in the nasal and pharyngeal catarrh did not quite reach the finality of cure. Further attention to the circulation of air between the middle turbinate and the septum was speedily successful. The fault in these cases lies in the lack of proper flow in inspiratory air in the upper chambers of the nose. This may be due to a naturally close proximity of middle turbinate and septum, or the result of injury, or again very commonly to an hypertrophy or edema of the septal mucous membrane produced by the negative pressure of ineffectual efforts to breathe through the upper regions of the nose. A compensatory shrinkage of the mucous membrane covering the inferior turbinates sometimes takes place in these cases, so that the inspired air passes eventually too easily through the lower channels of the nose, with as disastrous results to the lungs as in mouth breathing.

It is interesting to note that insufflations of tubercle bacillary emulsion will sometimes cure asthma, and sometimes aggravate it. In the latter case the patients speedily benefit by treatment directed towards the establishment of a proper inspiratory current, and attention to spots either on the middle turbinate or septum obviously hypersensitive from overwork.

Immunity in tuberculosis depends on the proper anatomical relationship of the middle turbinate bone to the septum nasi, and the physiological capacities of the epithelial cells in the upper regions of the nose.

Catarrh of these latter structures is never chronic, if the inspiratory current is proper and adequate. On the other hand, paradoxical as it may seem, with an imperfect current tuberculous catarrh is extremely probable, and in my opinion, this is the nature of 80 per cent. of the cases which are classified broadly as chronic nasal catarrh. Fortunately this is of merely academic interest, since it is easily cured.

HEART MURMURS AND HEART DISEASE IN CHILDREN.*

By G. WERLEY B.S., M.D.

EL PASO, TEX.

EVERY examination of the heart in children must have as its prime object the question of prognosis; for the child's whole future may depend upon our decision. Our verdict may mean for the child a life of restriction, half-living, and thwarted ambition, or it may mean hope and a joyous looking forward to all that life may hold. To become proficient in the examination of the hearts of the young is worthy our best efforts and most earnest study. Other things equal he will be the best diagnostician who has the most knowledge at his command. Let us then consider a few facts:

In what percentage of children under ten years of age may we expect to find acquired heart disease?

Norris examined the statistics in two Philadelphia hospitals and one in Boston and found that among 16,120 sick children, heart disease was present in 1.4 per cent. Deutsch[1] found only 0.17 per cent. of chronic valvular disease in 52,281 cases of sick children collected from various German hospitals. Of 250,000 school children examined by school inspectors in New York City in 1918,[2] 1.6 per cent. showed cardiac defects. Of 28,000 school children in New York's lower east side, 700 were thought worthy of note because of some cardiac irregularity. These 700 cases were then passed upon by Dr. Robert Halsey and his staff of assistants at the Cardiac Clinic of the Post-Graduate Hospital; 167 were found to have organic heart disease. The other 533 of these 700 suspected cases were found to be functional and not organic. So among these 28,000 children there was about one in 200 with genuine disease of the heart. The statistics last cited show that the ordinary examiner suspects cardiac disease about three or four times too often. Applying this deduction to the 250,000 school children examined by school inspectors in New York City gives an actual incidence of about one-half of one per cent. of heart disease. The correctness of this estimate, I think, is confirmed by the fact that Norris found only 1.4 per cent. among 16,120 *sick* children. The statistics here collected embrace 346,401 cases and it would seem our deductions must come pretty near to giving us the truth. The high incidence of heart disease in the German Hospital of New York City (24 per cent.) and in the Great Ormond St. Hospital in London (10 per cent.)[3] must find an explanation in the special class of cases attracted by certain clinics.

Endocarditis is almost unknown in infancy. Holt found not a single case in over 1000 autopsies in children under three years of age.[4] In a personal communication Dr. Holt says that his further experience does not modify this statement. He also voices the opinion that much undue alarm is caused by the diagnosis of valvular disease where it does not exist.

Of 145 cases under 15 years of age, Holt found 14 under 5 years of age and 71 from 5 to 10 years of age. The age incidence of 150 fatal cases reported by Lees and Poynton was, up to 3½ years 1, first 5½ years 18, 5½ to 10½ years 105. In the second five years of life, heart disease is found about five times oftener than during the first five years. The only way to determine definitely and beyond question the incidence of organic acquired heart disease in children would be by the examination of large bodies of post-mortem statistics collected from hospitals for children. After much correspondence I have met with no success in gathering such information.

The question of acquired heart disease in children resolves itself largely into a study of rheumatism in its various manifestations. All the pediatricians whose works I have consulted, Fisher, Holt, Griffith, Kerley, and others, agree in assigning rheumatism as the cause in from 90 to 95 per cent. of all cases. White and Reed[5] hold that "rheumatic infection is almost the sole cause of chronic change in the mitral valve." This is in agreement with Cabot's[6] opinion that "no infection except the form of streptococcus manifested in rheumatism and chorea and primary acute endocarditis bears any known relation to mitral stenosis." Poynton[7] goes even further and says that "the peculiar effect of rheumatism upon the nervous system tends to produce disturbances of the heart, such as tachycardia, precordial sensations, irregularity of action, and even anginal symptoms." Chronic myocarditis is not common in children, but when found, we may generally look upon rheumatism as the cause.

Since rheumatism plays such an important rôle in the cardiac diseases of children the recognition of that ailment assumes first importance. Swollen, red, and tender joints are not always present. Rheumatism may manifest itself as a purpura, erythema multiforme, as rheumatic nodules, as chorea, pharyngitis, tonsillitis, muscular and growing pains, or primary endocarditis. Endocarditis is much more likely to complicate rheumatism in the child than in the adult. Scurvy, joint tuberculosis, and suppurative arthritis are to be differentiated from rheumatism.

Barker[8] is of the opinion that in children infectious (rheumatic) arthritis seldom has its origin in the teeth but is almost always due to tonsillitis, adenoids, or infected sinuses. Poynton thinks that chronic nasal and middle-ear catarrh may also be related to rheumatism. Unfortunately removal of foci of infection does not always prevent the recurrence of rheumatism. Some 30 per cent. continue to suffer as before (St. Lawrence). Established valvular disease is not helped by removal of the primary focus. I believe that more attention should be paid to discovering the primary cause of tonsillar and other head infections in children. My own belief is that stuffing with sweets and candies is largely to blame for the excessive prevalence of catarrhal infections and bad teeth in American children. It is my impression that among Mexicans, whose diet is more simple, tonsillitis and rheumatism are less common, also endocarditis.

The endocarditis of the infectious diseases does not frequently result in valvular deformity. This type of endocarditis is most frequently fatal. When recovery does occur, the cause does not persist and the damage is repaired with little resulting deformity. It is the persisting, chronic, slow-acting dis-

*Read before the El Paso County Medical Society, March, 1921.

ease that causes valvular deformity, such as rheumatism, syphilis, and sclerosis. Syphilis is not a common cause of heart disease in children. Of 84 children examined by Halsey at the New York Post-Graduate School, all suffering from chronic cardiac affections, only one gave a positive Wassermann reaction. At the same time 8 per cent. of these children had aortic insufficiency. Rosenberg[11] found only 4 cases of endocarditis in 1770 cases of scarlet fever. Acute endocarditis in influenza is rare,[12] but subacute endocarditis is a quite common and fatal sequela.

The two most common findings that cause suspicion of heart disease are irregular pulse and the presence of a murmur. Neither of these considered alone makes certain the presence of heart disease.

All forms of irregular pulse have been brought into seven varieties by the studies of Lewis, Mackenzie, and others. They are as follows: (1) Heart block; (2) Paroxysmal tachycardia; (3) Auricular flutter; (4) Auricular fibrillation; (5) Premature beats; (6) Sinus arrhythmia; (7) Pulsus alternans.

The only common form of irregular pulse in children is that due to sinus arrhythmia and that is purely physiological and is a sign of a normal heart. To take up these forms seriatum: Heart block is almost never seen in children. Of Lewis' 42 cases none were under 10 years of age.

Paroxysmal tachycardia occurs at all ages after the first decade. Lewis says that a single instance has been recorded in a child of 6 years. Through the kindness of Dr. W. L. Brown I was able to study the case of a girl in whom the attacks began at 12 years.

None of the 27 cases of auricular flutter observed by Lewis were under 20 years of age.

Premature beats are common in adults. They are of no value in determining the presence of heart disease. Of the 114 cases studied by Lewis only 2 were under 10 years of age. I have recently seen a case in a boy of 7 years sent to me by Dr. Jim Camp of Pecos, Texas. "Pulsus alternans goes with angina pectoris, high blood pressure, and fibrotic myocarditis," and is practically never seen in children.

Auricular fibrillation belongs to mitral stenosis and chronic myocarditis. Hart, in a personal experience of over 300 cases, saw only one under 10 years of age.

One may sum up the subject of the pulse as a diagnostic factor in the heart diseases of children by saying that in those rare cases where it points to cardiac defect the signs at the heart are generally unmistakable; and where the heart presents no abnormal physical signs the irregular pulse is of no significance. In at least 9 cases out of 10 the form of irregularity will be sinus arhythmia, a perfectly innocent physciological state of affairs.

If there is one error that dies hard it is the common belief that a heart murmur means a defective valve. Nothing is further from the truth, especially in the young. Lüthje examined 854 school children and found a functional systolic murmur in 612 (71.6 per cent.). Prof. Ruldolf[13] found functional heart murmurs present in 60 per cent. of the inmates of the surgical wards of the Sick Children's Hospital in Toronto. Hamill and Le Boutillier found accidental murmurs in 66.2 per cent. of 80 school children examined. This is not the place to discuss functional murmurs, but in many children exercise, excitement, or even a hot bath may cause murmurs to appear. The heart readily dilates in children, and in the presence of anemia and debility this may be more marked, causing valvular incompetence from stretching of the mitral ring. Lee Rice[14] of Galveston, Texas, studied functional murmurs in 303 soldiers. After 5 days' rest in bed the murmurs all disappeared except in 22 men. This shows how dangerous it is to reach conclusions from a single examination and how uncertain cardiac murmurs are in their diagnostic value.

I will conclude by setting down a few cautions and reminders:

1. The history is all important in making a diagnosis of heart disease in children. If there is no history of rheumatism in any of its manifestations the chances of making a mistake are greatly increased.

2. Remember that acquired valvular disease is extremely rare during the first three years of life and very uncommon up to the fifth year.

3. Remember that a systolic murmur alone is never sufficient to establish a diagnosis of valvular disease.

4. Remember that the heart of the child is extremely sensitive to vagus influences and the irregular pulse of a child is far more commonly physiological than pathological.

5. Remember that large collections of statistics show the comparative rarity of acquired valvular disease in children, much less than one per cent. of those under 10 years of age. Alarming statistics from hospitals that draw an excessive percentage of heart cases are not to be considered without explanation.

6. Remember that in children pain about the heart, palpitation, shortness of breath, fainting, and the like are generally due to an unstable nervous system and are not due to heart disease.

7. Diastolic murmurs, definite and permanent cardiac enlargement, a heaving apex beat, definite and well-marked thrills, heart block not due to drugs, auricular fibrillation, are reliable findings in making a diagnosis of organic heart disease. These are late symptoms. In children the diagnosis should be that of prospective heart disease so that actual and serious disease may be prevented.

401 ROBERTS BANNER BUILDING.

FRIGIDITY AND STERILITY IN THE FEMALE.*

By B. S. TALMEY, M.D.,

NEW YORK.

THE purpose of life is shrouded in deep mystery. The aim of creative evolution is unknown and apparently unknowable. Still, judging by appearances—and our entire knowledge is derived from the world of phenomena—the goal of life is to create new life. Sterile life is life wasted. Only the abnormal, the degenerate desire to remain sterile out of choice. The impulse for the preservation of the race is as imperious as the instinct of the preservation of the individual. Both impulses are interdependent. Without the individual there can be no race, and without a race the individual is unthinkable. The individual must procreate to create a race, and the desire for procreation, in the higher animals, stands in close relation to the impulse of copulation. The impulse for copulation is hence transcendental, the attraction of the sexes is mysterious like the attraction of the magnet to the iron, like life itself, like the universe, like the Creator and His creation.

Copulation is conditioned upon three faculties or potencies, and procreation requires an additional potency. There is necessary (1) the potency of voluptas, or the transcendental desire of the individuals of the two sexes to unite, (2) this union must give the two parties a certain satisfaction or libido. Where libido is lacking, union becomes disgusting and is avoided altogether. (3) There must be the facultas coeundi. If such faculty is missing either through lack of male erection or through the absence of the vagina or other female obstacles, then union is impossible. To these three requirements there is added for procreation another potency, the facultas generandi. There must be present living healthy spermatozoa and normal ova, and the genital tracts of both sexes must be pervious. If one of the four faculties is missing the individuals are suffering from impotence.

Idiopathic impotence of voluptas, except in the very young or in extreme old age and in homosexuality, is exceedingly rare. There is seldom an individual met with who is not more or less attracted by the opposite sex, who is lacking all sexual feelings. Inherited frigidity, or complete sexual indifference towards the other sex, the complete "natura frigida," is very seldom found except in low idiots. Sexual anesthesia is, as a rule, an acquired anomaly. When the gonads are degenerated or removed in early youth, the person is irremediably non-sexed, his attraction to the other sex is decreased to zero.

The second impotency is that of libido. This sexual deficiency is falsely misnamed frigidity. These patients are not frigid or cold at all, on the contrary, their desire for copulation is, as a rule, considerably increased, but they cannot find the desired satisfaction or libido in normal coition. This impotency is quite rare in men, but is quite frequent in women. These women have a great difficulty to experience the orgasm, or the orgasm is never experienced. The patients are thus suffering either from relative or absolute orgasmus retardatus.

The orgasmus retardatus may be real or only apparent. If the husband is suffering from ejaculatio præcox, then naturally the female orgasm will be retarded in relation to her husband's precipitated ejaculation. The real retarded female orgasm is mostly found in women who had practised excessive masturbation in their youth. This practice generally consists in an overstimulation of the clitoris at the expense of the cervix, which is the main participant in the copulative female orgasm. Through long and excessive masturbation the sensitiveness of the clitoris is greatly decreased. The copulating stimulation by the male organ does not suffice to evoke the summa libido. It requires a pulling, squeezing, pressing, or rubbing by stronger organs, such as thighs or hands to furnish the desired satisfaction. Only these organs which are capable to offer continuous stimulation are able to evoke the orgasm, the caducous penis never. Such women only experience fore-pleasure and remain dissatisfied. Never reaching the acme of libido, the patient is constantly avid for repeated union. Frigidity in her case is a misnomer altogether. It should rather be called calidity. She appears to be more passionate than her normal sister. She is lascivious and lustful in her manners. She is constantly on the alert for strong men. To the outsider she appears to be sex-obsessed, an erotic dynamo. Katherine of Medici and her namesake, Katherine of Russia, both suffered from orgasmus retardatus. An entire regiment of her guards could not satisfy the latter. She was sexually deficient. She suffered from the impotency of experiencing libido. Still she was not frigid. She had normal desires.

In the apparent or relative orgasmus retardatus, the woman is perfectly normal and is surely not frigid. The trouble lies with the husband who is suffering from precocious ejaculation, or it is caused by coitus interruptus. Normally the female orgasm appears a moment later than the male ejaculation. In this way the suction of the uterus* facilitates the entrance of the spermatozoa within the cavity of the cervix where they are lodged in an alkaline surrounding and thus secure against the deleterious effect of the acid vaginal contents. It is hence apparent that in coitus interruptus the female will seldom reach the orgastic stage. Scarcely does a day pass without some woman confessing to the writer that she has never reached the acme of libido.

In absolute impotentia of libido, the patients often break the rules of conventional morality. The moral woman who after long experience has found little satisfaction in union will finally become disgusted and try to avoid copulation altogether. In this sense the patient may be said to be frigid. But she only appears frigid; in reality she is calid.

*Read before the Eastern Medical Society, March 11, 1921.

*Three American authors have observed the suction of the uterus during the orgasm: Mundé (*Amer. Journ. Obstetr.*, vol. xvi, p. 846), Beck (*St. Louis Med. and Surg. Journ.*, September, 1872, p. 449), and Talmey (*N. Y. Med. Journ.*, June 23, 1917). Still there are enough doubting Thomases met with in American medical literature who do not believe in this uterine action. If a European professor had published such an observation, no American author would dare question its truth.

Her deficiency lies in the impotency of experiencing libido.

This lack of the female orgasm leads not seldom to the fourth impotency, the impotentia generandi, or to the sterile marriage. Sterility was and still is considered the greatest calamity that can befall the family. The ancients punished barrenness by the dimissal of the wife. They judged by appearances. The female conceives, carries, gives birth, and nourishes the child. Hence where there is no child she is at fault. The Roman law allowed the putting away of the wife for infecundity. Among the Hebrews a divorce was granted to the husband after ten years of childless wedlock. Nowadays we know better. Such a divorce should be granted to the wife and the husband should not be allowed to remarry. For in the great majority of cases it is the husband who is directly or indirectly the cause of sterility.

Idiopathic sterility is a rare occurrence even in the female. Absence of vagina, fetal or rudimentary uterus, absence or imperviousness of the tubes, absence or fibrous degeneration of the ovaries are not met with every day. Even the anomalies causing relative sterility, or a sterility which could be corrected by an operation, are quite rare. Few physicians have often seen an atresia vulvæ, vaginism, rigidity of the hymen, hypertrophy of the rugæ, excessive acid reaction of the vaginal contents, elongation of one lip of the cervix, thus covering apronlike the external os, stenosis of the os or of the cervical canal, polypi of the uterus, or exaggerated uterine deviations. All these anomalies will scarcely form one or two per cent. of the female sterility.

What the average medical man does find in sterile women are all kinds of inflammations, and the latter are seldom her fault. Inflammations of the carunculæ myrtiformes, or of the Bartholinian glands, endocervicitis, endometritis, metritis, perioophoritis, ovaritis, salpingitis, perisalpingitis, perimeteritis, etc., are, as a rule, caused by a gonorrhea of the husband. These inflammations form the main cause of female sterility. All the causes of idiopathic sterility, absolute or relative, are insignificant in frequency compared with male gonorrhea as the cause of sterility in the female.

The prophylaxis of female sterility is hence male abstinence from extramarital relations, especially from meretricious venery. If a generation or two would abstain from any relations with prostitution all venereal diseases would entirely disappear, and with this disappearance 90 per cent. of female sterility would pass from view forever.

The therapy of sterility must aim mainly at the removal of the main causes of sterility, endometritis and pelviperitonitis. These two afflictions are causes of sterility par excellence, and they are just the lesions seldom or never amenable to surgical treatment. Here electricity is almost the only remedial measure promising success. Electricity promotes the nerve tone, increases muscular activity, and quickens circulation. When the current passes through living tissues, the interpolar action of the positive pole, by contracting the capillaries is anodyne, sedative, anticongestive, denutritive, and antihemorrhagic. The interpolar action of the negative pole, by increasing the blood supply, is stimulating, congestive, derivative, and alternative, thus favoring absorption. These physiological qualities make electricity the best remedial agent in the treatment of endometritis, metritis, salpingitis, ovaritis, and pelviperitonitis.

Electric treatment has one serious drawback. The presence of pus must be excluded. Where there is pus, electricity is very dangerous and is strictly contraindicated. It may change a dormant innocuous suppuration into an acute suppurative process. But when, by a perfect diagnosis, pus can be excluded there is no better remedy than electricity in all catarral inflammations within the female pelvis.

Electricity is the remedy par excellence in sterility caused by orgasmus retardatus. The sexual excitement and orgasm of the female are not irrelevant to impregnation, as quite a few medical writers would like to make us believe. Dispareunia and lack of orgasm is not rarely the cause of sterility. Real orgasmus retardatus in the female is almost invariably caused by early masturbation which has permanently weakened the genital nerves. These weakened nerves are greatly benefited by the electric tonic.

Before beginning such electric treatment in orgasmus retardatus, it is necessary to ascertain first whether we are dealing with a true retarded female orgasm or only with an apparent retardation, the result of premature ejaculation in the male. In the latter anomaly, entrance into the vagina is effected with a fairly good erection, but immediately upon the entrance ejaculation takes place and the penis wilts. This ejaculation does not come in jets, and the sperma is rarely deposited at the mouth of the cervix. The premature flaccidity of the male organ accounts for the absence of the female orgasm, and the aspiration of the sperma into the uterine cavity does not take place. The spermatozoa have to rely upon their own motility to reach the uterus. Very often they fail, and the result is sterility. The Talmud knew this centuries ago; it says: "Kol shichvas zera sheano iorah kachez mezehas (Niddah 43a)," "a spermatic emission which does not shoot forth like an arrow can not fertilize." Spermatozoa deposited near the vaginal entrance, inside or outside of the vagina, may under exceptionally favorable conditions effect impregnation. But this will always be a very rare occurrence.

But this sterility is no more sterility in the female. The woman is entirely normal. It is the male who suffers from a kind of impotence. If such a man, suffering from premature ejaculation, be mated to a woman suffering from orgasmus præcox, the orgasm will appear in both mates synchronously, and the couple may be quite prolific. There is a perfect compatibility between such mates, just the same as if a sadist is married to a masochist, the couple may be considered happily married. Compatibility in marriage is always relative, never absolute.

In conclusion let us always bear in mind that of the four impotencies: (1) Impotentia voluptatis, impotence of voluptas, or absence of desire for erotic union, or true frigidity, the natura frigida, as the ancients called the anomaly, is exceedingly rare in men or in women. The transcendental attraction between the sexes is never absent in man

from infancy to old age. (2) Impotentia cœundi, the idiopathic impotence of copulation is also a rare occurrence in either sex. But the pathological or rather acquired impotentia cœundi is the impotence par excellence in the male, while in the female it is exceedingly rare. In acute genital inflammation copulation may be made difficult on account of the pain, but this is not real impotence in the strict sense of the word. If the woman is willing to bear the pains copulation is possible. (3) Impotentia libidinis, the idiopathic impotence of libido where the individual does not derive the least pleasurable feeling from erotic union is very rare. It is sometimes found in men in cases of grave neurasthenia. In women, on the other hand, this anomaly is the impotence par excellence. It is falsely misnamed frigidity; it ought to be calidity. The patients are not cold at all. (4) Impotentia generandi, the idopathic impotence of fertilization or sterility is also rare in either sex. But the acquired impotence of procreation is exceedingly frequent. Half of the sterile marriages are due to azoospermia of the male as a result of gonorrhea, and at least ninety per cent. of the other half, due to the female inability to procreate, is also caused by the infection the wife had received from her husband. It was ignorance which attributed the cause of sterility to the female. It is the husband who is, if not the immediate, at least the remote cause of even female sterility.

155 WEST 118TH STREET.

A REVIEW OF THE BLOOD AND URINE EXAMINATIONS IN 200 CASES OF CHRONIC FOCAL INFECTION OF ORAL ORIGIN.

BY ALBERT M. CRANCE, M.D.,

GENEVA, N. Y.

ACKNOWLEDGING that the subject of focal infection has been written upon to an almost exhaustive extent, there has, however, been little said or written about the effect of chronic infection of this type upon the blood and urine pictures. In reviewing two hundred cases which were definitely classed and diagnosed as focal infection, there has arisen a definite conclusion to be drawn therefrom. A total number of 1,574 cases were reviewed in order to obtain 200 clear-cut focal cases. In such instances where tuberculosis or syphilis might even have been a suspicious factor, they were stricken from the list.

Review of Cases.—One hundred and two were males; ninety-eight were females. 179 of the cases presented definite dental infection, out of which number 118 showed definite apical abscesses, either with or without pyorrhea. Sixty-one of this number showed pyorrhea and rarefaction alone with no apical abscesses.

157 cases showed definite infection in the tonsils. 151 cases presented enlarged submaxillary nodes.

Blood Examination.—The average haemoglobin was 75.8 per cent.

The red-cell count was apparently but slightly affected. Only eleven, or 5½ per cent., of the cases gave a count below four millions.

The white-cell count may be tabulated as follows:

No. of Cases		Percentage of Cases
58 ranged between	6000 and 6800.	29
55 ranged between	5000 and 6000.	27.5
9 ranged between	4000 and 5000.	4.5
3 ranged between	3000 and 4000.	1.5
0 ranged between	2000 and 3000.	0.0
1 ranged between	1000 and 2000.	0.5

In other words 63 per cent. of the cases showed a definite leucopenia.

A differential count was made in nearly all of the cases, but there was found to be very little deviation from the normal. There was apparently nothing of definite interest.

Urine Examination.—The urinary findings are very interesting. One hundred twenty-four, or 62 per cent., of the cases showed a definite albuminuria, out of which 90, or 45 per cent., were in class 1, 23, or 11.5 per cent., in class 2, 5 or 2.5 per cent., in class 3 and, 6 or 3 per cent., in class 4.* Two, or 1 per cent., of the cases gave a positive sugar reaction.

Discussion.—There are apparently two outstanding features in cases of chronic focal infection. One is that the majority show a leucopenia; the other is that a high percentage of the cases present an albuminuria. The fact, that a leucopenia in any given case is an evidence of lowered body resistance, gives rise to an important factor in treatment, whether it be medical or surgical. It seems perfectly obvious that, if certain foci of infection are keeping the body resistance in any way below normal, the foci should be removed before the best results may be expected to be accomplished. The fact that 62 per cent. of the cases showed a definite albuminuria seems to be quite sufficient evidence of the relationship between oral infections and albuminuria. In this paper, the writer does not desire to discuss the treatment of albuminuria, but it may be mentioned that by removing chronic foci of infection in such cases it has been observed that the albumin disappeared in a rather high percentage.

Conclusions.—In this series of 200 clear-cut cases of focal infection, 63 per cent. showed a definite leucopenia and 62 per cent. a definite albuminuria.

DIETETIC TREATMENT OF CANCER.

BY THOMAS J. ALLEN, M.D.,

EUREKA SPRINGS, ARK.

IN a former article on "Food Combination (MEDICAL RECORD, July 2, 1921), I stated the reasons for concluding that the constitutional factor in cancer, its fundamental cause, is variation in feeding. I shall now state briefly the indications for treatment and for prevention drawn from that etiology.

Cancer is a more serious scourge than war, and thus far as difficult to control. But when we consider that the cells of the body have an individual, an independent, as well as a collective existence, it is a wonder that not more than one woman of every eight and one man of every eleven, above 45, now dies of cancer, while the rate increases in all civilized countries.

Cancer is a reversion in cell growth, incited locally by some form of irritation; but it is now generally agreed that there is a constitutional fac-

*Classes 1, 2, 3 and 4 refer to the degree of albuminuria—1 noting a definite small amount of albumin, and 4 an albuminuria of very severe degree.

tor, which establishes a predisposition, and the fact that it is not hereditary nor infectious, and that the liability of occupations, of races and of localities, varies greatly, clearly indicates that the major factor is some habit of living. As explained in the preceding article, the statistics, properly considered, clearly point to "something in the food," as Bertillion concluded, and this seems to be variation.

Harmony in cell growth prevents giantism, and we have abundant evidence to conclude that variation, always imminent, is prevented in the same way—through the secretions. Metchnikoff quotes Arnold in support of his view that defense against cancer is in some way effected by the internal secretions. It is clear from the reasons given in the preceding article how the digestive secretions may be disorganized by variation, and it is reasonable to conclude that the internal secretions are controlled by the digestive, the primary. It would follow, then, that the first step in the treatment should be to restore the balance by proper food; and, since the cancer rate doubles and trebles with increased variation, as shown by the statistics in the preceding article, it follows that it could be materially reduced by reducing variation. This implies a change in fundamental habits, but, improvement in nutrition is followed by an improvement in the relish for simpler, more wholesome food, that well repays the effort.

While I was formerly engaged in the treatment of chronic diseases, I frequently undertook the management of cancer cases; and, from considerable experience, I have concluded that cancer might be reduced as much as we have reduced tuberculosis in the past twelve years, since we gave up looking for a specific "cure," and began to treat it as a disease of faulty nutrition.

The search for a specific germ and a specific "cure" for cancer must prove futile. Parasites may in some instances furnish the local irritation that stimulates the cells to malignant growth when the constitutional condition is favorable, but the fact that cancer is not infectious indicates that there is no specific bacterium.

The same inherent forces that we know to be at work when typhoid fever, for example, has been established, overcoming the invader and providing for defense against it in the future, must be at work in every case of cancer. Occasionally the curative power, the *vis medicatrix naturæ*, prevails, even when hope has been abandoned; and, it is the proper aim of scientific treatment to aid these natural forces. We know how to do this in the case of boils, and, by the way, the invariable success of the yeast and charcoal treatment has emphasized the importance of constitutional treatment in that instance.

It is reasonable to suppose that, immediately the first reversionist cell asserts his amebic power of separate existence, the forces favoring organic organization are arrayed against the renegade. As in tuberculosis, these defensive forces often succeed in restoring the normal condition without our special cooperation; but, in cancer especially, there should be no delay. Experimentation with mice has shown that early removal of the tumor is favorable to recovery, but exclusive local treatment is wholly unwarrantable, and surgery may not always be the best local treatment. The evidence for the variation theory is so strong that proper dietetic treatment should not be neglected.

In the New York Cancer Hospital, in the Battersea, London, hospital, and others, a low protein diet has been used with good results. A diet that excludes flesh materially reduces variation; but the fact that the Eskimo and cannibals are immune and that the Salisbury exclusive beef diet is used with apparent success in the treatment of cancer, and that a few protein diet has been found better than a low protein indicates that an appropriate "few protein" (Bishop) or single protein diet, possibly a flesh diet, in some cases, would be better. An exclusive milk diet has been used with success.

In a case diagnosed carcinoma by several Pittsburgh physicians, I used (with other treatment, of course) a diet of whole wheat bread and milk, with cottage cheese, exclusively for eight months, with permanent success. In another, an extreme case, given up after the subject had been prepared for operation at the Galesburg, Ill., hospital, whole (brown) rice, with raisins, prepared in the fireless cooker (a complete, low-protein diet) was followed for more than a year, the patient recovering slowly and remaining well for nearly four years.

Changes in diet should be made gradually; and now the subject's likes and dislikes should be duly considered. I mention these two cases as illustrating the view that the chief consideration is uniformity of diet, the one using much cheese and milk with whole wheat being a rather high protein, the other quite low, but both proving successful.

Medicolegal Notes.

Erroneous Instruction as to Negligence in X-Ray Case.—The New York Appellate Division holds that it is error to give, in an action against an *x*-ray specialist for injuries to a patient in treatment, an instruction to the jury that the result of the particular treatment (which caused sores) might be regarded as some evidence of negligence, it having been proven that that specific result might come from proper treatment without negligence on the part of the physician in the case of a hypersensitive person, a disposition of the patient which cannot be known in advance of the test of actual treatment and its results.—Antowill v. Friedmann, 188 N. Y. Supp. 777.

Medical Opinion Based on Plaintiff's State of Prior History Held Inadmissible.—In a personal injury case, in which injury to the plaintiff's eyes was one of the alleged results, it was held that reversible error was committed in the examination of the plaintiff's expert witness on the question of whether the condition of plaintiff's eyes, arising from the injury sued for, was permanent. Over the objections of the defendant, the doctor was permitted to state that he learned from the plaintiff the condition of her eyes prior to the injury, but was not allowed to state what he learned. Thereafter the hypothetical question was put by plaintiff to the doctor, and among other things submitted as a basis for his opinion was what the expert had learned from her as to the prior condition of her eyes, couched in these words: "And taking into consideration further what you obtained from the examination of her with reference to her history." This was held error. The court said: "This was a very vital matter. The defendant had evidence tending to show that plaintiff was in an unfavorable condition prior to the injury, and many of the conditions claimed to have arisen from the injury are clearly shown to be conditions which might well exist in a young girl from other causes than the injury, which, according to defendant's evidence, was slight."—Borowski v. Wiles Biscuit Co. (Mo. App.), 229 S. W. 424.

COMPRESSED AIR IN MEDICINE.

A FEW weeks ago there appeared in the *Lancet* (August 13, 1921), the account of some interesting experiments on cats by H. H. Dale and Leonard Hill, whereby it was shown that these animals cannot be deeply anesthetized by nitrous oxide and oxygen until a certain degree of asphyxiation has been induced.[1] It then occurred to them to try the same mixture—eight parts of nitrous oxide to one part of oxygen—in the compressed air chambers at the Lister Institute. There was no difference in the mode of administration save that the air pressure was raised to about one and a half atmospheres. Deep anesthesia without any deficiency of oxygenation was brought about in this way. The extra half atmosphere of pressure would seem to have been sufficient considerably to increase the partial pressure of nitrous oxide and, at the same time, to bring that of oxygen nearer to that of sea level.

So impressed have the authors of this paper been by the results of their investigations that they recommend an operating room, constructed as a pressure chamber, and provided with an appropriate lock for ingress and egress. In a chamber of this sort they are convinced that deep anesthesia, without asphyxiation and without subsequent symptoms of poisoning may be obtained in the human subject. Mixtures of four, five or six parts of nitrous oxide to one of oxygen could, in their belief, be used in this way.

Apropos of these suggestions it is a matter of both interest and simple justice to recall that the eminent French physiologist, Paul Bert, not only made similar proposals more than forty years ago, but constructed a large pressure chamber, wherein operations were successfully performed on the human subject under mixtures of nitrous oxide and oxygen.[2]

In a paper read before the Academy of Sciences, November 11, 1878, Paul Bert said: "If we suppose the patients placed in an apparatus where the pressure can be raised to the equivalent of two atmospheres, the necessary tension will be secured by respiration of a gaseous mixture containing 50 per cent. of nitrous oxide and 50 per cent. of atmospheric air." We know of at least one physician of this city who, while a student of medicine in Paris, witnessed an operation (amputation of the thumb) performed by the late French surgeon, Péan, under this plan of anesthesia.

The next considerable advance in the use of compressed air in medicine was made by Dr. J. Leonard Corning, whose experiments and observations were suggested to some degree by his study of the pathogenesis of the caisson disease,[3] but likewise not a little by what he was able to glean of the immediate effects of compressed air upon those laboring in it. After referring to the undertakings of Paul Bert with nitrous oxide and oxygen Corning remarks that, "The objects of which I have been in search are quite different from the foregoing, and have reference not to the introduction of the remedy but to the *enhancement* of its effects *after exhibition*. . . . I shall endeavor to show that by far the most useful service derivable from compressed air is found in its ability to enhance and perpetuate the effects of soluble remedies (introduced hypodermically, by the mouth, or otherwise) upon the internal organs, and more especially upon the cerebrospinal axis."[4] This increase, this intensification of effect, is, without doubt, due to the augmented blood pressure within the body and more especially within the craniospinal canal, the increased pressure giving rise here to enhanced exosmosis in the capillaries of the brain and cord. That such increased blood pressure occurs within the internal organs is shown by the increased diuresis commonly observed in those under air pressure. The increase in pulse rate and blood pressure is likewise significant.

Space does not permit a more detailed account of Corning's achievement in this interesting field, nor citation of the numerous cases in which he made use of the principle above enunciated. We may add, however, that one of his recommendations discloses a rather unusual sense of psysiological fitness—that in which he sought further to localize the effects of treatment upon the intracranial organs by moderate instrumental compression of the jugular veins.[5] This expedient he resorted to in the management of certain forms of migraine. The whole question of the use of compressed air in medicine makes a strong appeal; it is matter for regret that the apparatus required is so elaborate and so expensive.

FOOD VALUES.

UNDER the auspices of the Red Cross in Vienna 200,000 unfortunate children are being fed on a diet prescribed on the strict lines of a Teutonic theory, but—and let us be thankful—there are two mitigating circumstances. The first is that the Lister Institute and Medical Research Council of London have sent out Dr. Harriette Chick and Dr. Elsie Dalyell with a competent staff to apply, in alternate wards, newer principles arrived at by English-speaking physiologists. The resulting comparison is expected to send the Teutonic abstract theory to join many other of its predecessors. The second is that only the stubborn commonsense of the public and the coming of peace prevented physiologists from imposing rations based on the same principle on ourselves and the nations who are our friends. Dr. Gowland Hopkins, Professor of Biochemistry in the University of Cambridge, England, told the whole story in his recent Huxley Lecture delivered at Charing Cross Hospital. The human body, like the animal body, requires a diet composed of the substances known as proteins, fats, and carbohydrates. The experience of countless generations has proved that diet, to be healthy, must be varied, must contain fresh as well as prepared or dried substances, and—an all important fact—that individuals differ.

But Rubner, of Munich, elaborating experiments made by many men in other countries, established the proposition that the conservation of energy holds in the human body, and promulgated the non sequitur that if a diet conveyed into the body the proper quantity of energy, the constituents of the diet were a matter of indifference. The idol of the calory came into being and Americans and other benighted races were invited and, strange to say, almost on the verge of being compelled to worship it. Measure the number of calories by burning so much animal or vegetable protein, so much suet or butter or margarine or linseed oil, or sugar or molasses, and you will know the dietetic value of these foodstuffs. Rationing authorities of the army and navy, of all kinds of institutions, and even the International Commission which proposed to distribute the available food supply among the nations, were handed the calorimetric system as the supreme and only necessary criterion.

American and English science has now fortunately come to the rescue of commonsense. Biochemists have justified the natural craving for a varied diet. They have proved the existence of substances known as vitamines and these are in quantities too minute to be detected by calorimetry, but nevertheless are necessary for health. Although protein, fat, and carbohydrate can be measured by calories, they are not equivalents. A minimum of each must be present before the animal organism can take full advantage of the others. The calory theory of food leaves out factors quite as important as the ethers, neglected by those physiologists who pretend to judge liquors by their value in alcohol. When diets are being prescribed and constructed, the energy value, the presence of vitamines, and such admixture as provides the limiting minimum of each chemical constituent, must be taken into consideration and allowed for. Perhaps we may be allowed to venture on a prophecy. Diets constructed even on the most up-to-date principle will not be found to be entirely satisfactory. "One man's meat is another man's poison," and biochemists will have to go quite a bit further in their nice investigation of the chemistry of the body if they are to provide a guide to nutrition more satisfactory than that of a normal appetite combined with an educated palate.

INSUFFICIENCY OF THE LIVER IN GESTATION.

THE subject of hepatic insufficiency received something of a jolt on one occasion when some critic made the statement that experiments along these lines mean only that there is an insufficiency of the organism as a whole, but that any attempts to localize it especially in the liver are ill-founded. However, we can readily qualify assertions of this kind to fit the criticism, the distinction often being verbal rather than material. In *La Presse Médicale*, xxix, 43, 1921, MM. Crainicianu and Poper of Bucharest publish an article on the subject in question. They first refer to a case recently reported in Paris in which a woman seven months gravid was seized with severe symptoms of toxemia of pregnancy which ended fatally with the picture of acidosis. Autopsy showed complete degeneration of the livers of both mother and child, all other organs being intact. In such a case we are justified in speaking of insufficiency of the liver as an end result of some disease, but this apparently has little in common with functional insufficiency, or diminished function due to beginning structural disease, in which conditions we desire to ascertain the functional capacity of the organ.

The authors cite two cases recently reported in Bucharest in which there was fatal insufficiency of the liver after delivery, and which, although death may have been determined by the chloroform given during instrumental delivery, were evidently of gestational origin. The authors appear to believe that these rare fatalities are simply an exaggeration of some process which may be common in a mild form in the gravida as a class; and therefore suggest that we should practise some routine test for hepatic function, either in all gravidæ or in those in which there is reason to suspect incipient toxemia. The choice of a method is most difficult and they enumerate the objections to the tests in common use. They ultimately bring up a reported test proposed recently by Widal and associates, of an induced hemoclastic shock. In the normal subject the liver after a protein meal arrests any incompletely disintegrated protein, but if

the organ is unable to arrest these bodies, their entrance into the systemic blood causes a so-called hemoclasis. Such a test is perhaps the first on record which may be said to apply strictly to the functions of the liver to the exclusion of other organs.

To make a trial of this Widal test the authors studied forty-seven gravidæ who were, so far as could be determined, free from previous disease of the liver. Daily examinations were made of the urine and the digestive leucocytosis. The urinary analyses were for the purpose of determining any disturbance of hepatic functions. The conclusions are given as follows: in 20 per cent. of gravidæ examined during the last month of gestation there was urinary evidence of biliary retention; while in 33 per cent. the digestion leucocytosis was altered in the manner required to speak of hemoclasis. A higher type of the same condition is the simple jaundice of pregnancy and a still higher degree is icterus gravis, the maximum. The presence of the digestive hemoclasis should lead to suitable diet, or if this test is not made the presence of bile in the urine should lead to the same result. Indeed, to be on the safe side, all gravidæ may be placed on the diet for sparing the liver. Chloroform is contraindicated in obstetric operations while ether also attacks the hepatic cell. Hence nitrous oxide-oxygen anesthesia should be the choice.

THE DIAGNOSIS OF NOCTURNAL ENURESIS.

THE etiology of this distressing condition is too frequently overlooked in practice, hence the frequent failure to effect a cure. The first thing to be done is to distinguish between the so-called essential incontinence and symptomatic incontinence, therefore the urinary tract should first of all be explored. Congenital defects, phimosis, and urethral polypi should be looked for, as well as balanoposthitis and urethritis, while the rectum should be explored for hemorrhoids—they occur in children—fissure, rectal prolapse, and oxyuris. The examination of the rhinopharynx should not be neglected nor the spine—Pott's disease—nor the nervous system—myelitis, infantile tabes, etc.

Cystitis is a common cause of incontinence in young children, but the latter is then more likely to be diurnal and is accompanied by pollakiuria and severe pain on micturition. Blood may sometimes be present in the urine, which is usually cloudy or even purulent. Cystoscopy should invariably be practised, while a systematic analysis of the urine for albumin, chlorides, urates, or uric acid should be made, as well as a cytological one for blood or pus, while a search for the colon or tubercle bacillus will frequently be indicated. In cases of suspected renal or vesical tuberculosis animal inoculations and tuberculin injections should be carried out. Vesical or urethral calculi will produce enuresis, but it will then be both diurnal and nocturnal, while much pain will be complained of. Exploration with a metallic sound, a cystoscope, or a urethroscope will remove all doubt. The kidneys should be carefully explored; separation of the urines should be done whenever the least doubt exists as to the diagnosis, since incontinence is symptomatic of the early phase of renal tuberculosis.

The incontinence of epileptics occurs at the end of the paroxysm, is more prone to be nocturnal, and occurs at intervals. Examination of the patient's tongue for bites and great physical fatigue in the morning will reveal the true nature of the enuresis of the previous night. The incontinence of hysteria follows a severe emotion, while psychic treatment may settle any hesitancy as to the diagnosis. Incontinence from overflow is rarely observed excepting in cases of transverse myelitis; it is both diurnal and nocturnal. Incontinence from laziness can be controlled by keeping the child up late for several nights in succession, or the threat of punishment will have a like effect. Simulators are more difficult to detect. They must be closely observed, but in children the promise of punishment will usually put a stop to the enuresis. Simulation is rare in children and is more apt to be met with in adolescents, especially in soldiers. It must not be forgotten that enuresis may occur during convalescence from severe illness; it is then nocturnal and will be cured by proper feeding and tonics.

The examination should be completed by a careful exploration of the vesical and urethral sensibility, the contractile value of the vesical motor system and the other sphincters; finally, the state of the central nervous system should be examined into, as well as the family history in this respect. It is therefore clear that a complete examination —both medical and urological—should invariably be made in cases of enuresis in order to obtain an exact notion of the diagnosis of the cause of the affection before undertaking any form of treatment.

PLURALITY OF RABIES VIRUS.

FROM several sources of recent date have proceeded accounts of a double rabies virus. One of these was from Italy (Puntoni) and another report is a continuation of work begun half a score of years ago by Bouffard at the Pasteur Institute. This author relates (*Annali d'Igiene*) that in French West Africa a form of canine rabies is endemic which is not transmissible to man. The afflicted dogs present the paralytic form of rabies. There is an alteration of "personality" in these animals which causes them to be known as "mad," but not in the sense of being dangerous to man. The "mad" dogs bite, but of many men known to have been bitten not one has been known to develop hydrophobia. Researches on these dogs have been pursued by a number of French investigators, and no doubt occurs that the disease in question is rabies. The virus has been inoculated with positive results into various kinds of small laboratory animal—rabbits, cats, and dogs, and the animals convey the disease to their fellows by biting. An

immunity of the native African is not responsible for the absence of the disease in man, because the Senegalese have frequently exhibited ordinary rabies after mad dog bites. There is clearly a second virus which may or may not represent an attenuation of the first. There is not the slightest evidence of such attenuation and it is no less likely that the second virus, as suggested from Puntoni's experience, is a mutation of the original.

Spontaneous Syphilis (?) in the Rabbits

In case it is definitely proven that the rabbit is subject to an autonomous syphilis of the same nature as human syphilis, this discovery will be one of the most astonishing on record. It would be the irony of fate that science had selected the rabbit as an experimental animal for the study of human syphilis and had obtained a great deal of curious information without once having suspected that the same animal is itself subject to the disease. There seems to be no doubt that the rabbit suffers from a spirochetosis which is transmitted by coitus and that the disease bears a strong resemblance to experimental rabbit syphilis; further the spirocheta of the natural disease is morphologically identical with *Treponema pallidum*. This information comes from Scherejewsky, who, we believe, was the first to cultivate the latter organism. An abstract in the columns of *La Presse Médicale* for September 3, 1921, xxix, 71, contains the sensational information that a woman with recent syphilis and a positive Wassermann claimed to have been infected by a pet rabbit which had some eruption. The medical men who reported the case examined the rabbit and found lesions of the prepuce and anus which contained spirochetes which they assumed to be treponemata. There were four rabbits in the household of which three were females, one of the latter being intact, while the others presented lesions at the vaginal entrance and had a history of recent abortion. Other rabbits who mixed with the first lot became infected. The question arises, did the rabbits infect the woman or did the woman infect the rabbits? While not wishing to impugn unjustly the veracity of the author's patent, we nevertheless must regard the latter sequence as the more probable.

News of the Week.

The American Public Health Association announces that its fiftieth annual meeting will be the occasion of a Health Fortnight, extending from November 8-19. The celebration will include three main divisions: A Health Institute, November 8-11; a Health Exposition, the largest affair of its kind ever held in New York, November 14-19, and the fiftieth annual meeting of the American Public Health Association, November 14-19. To focus the attention of the general public upon this celebration, November 13 will be observed as Health Sunday in many churches, and the week will be marked by numerous business and social organizations. Speakers prepared to talk authoritatively on health topics will be furnished on request to any of these organizations. The New York Chapter of the American Red Cross is cooperating with the general committee in arrangement for this service. As a permanent souvenir of the semicentennial and as a record of the work accomplished, a Jubilee Historical Volume, entitled, "Fifty Years of Public Health," will be ready for distribution during the Health Fortnight. Further information regarding the semicentennial may be obtained from the American Public Health Association, 370 Seventh Avenue, New York City.

Cholera in Russia and the Near East.—The latest information concerning the cholera situation in Russia, laid before Dr. Rupert Blue, who recently arrived in Riga, in connection with his general investigation of the health conditions of emigrants likely to be bound from Europe to the United States, indicates that the cholera epidemic in Russia is on the decline. The situation is not so encouraging in that part of Armenia which was the scene of war between the Turks and Armenians last winter. Here a population of 500,000 homeless and facing famine are falling an easy prey to the disease.

Child Health Work in Austria.—The new medical program of the American Red Cross, which went into effective operation on July 1, has given a new impetus to Austrian child health work. The Red Cross has taken over one hundred child health stations which were about to close for lack of funds, and has guaranteed financial support for a period of one year. Forty-one of these child health stations are located in Vienna. These will continue under the direct control of the respective organizations that have been administering them, with supervision by the American Red Cross. Because of lack of trained workers, it was decided to establish a short practical course in the care of infants and young children with lectures on social subjects. All nurses in charge of centers are required to take this course and the examinations which follow its completion. At the present rate of Austrian exchange the cost of operation for each station is considerably less than $1000 per year.

Plans for Scientific Research Among the Eskimos.—The School of Hygiene of Johns Hopkins University is preparing plans for an expedition into a region hitherto unvisited by white people for the purpose of studying problems of dietetics, nutrition, and sex among the Eskimos. Dr. Victor E. Levine of the Creighton School of Medicine, Omaha, Neb., was sent during the early part of September with a small party from Battle Harbor into the Eskimo country for the purpose of making a preliminary survey, particularly with regard to climate. It is because the Eskimos are said to be the healthiest people in the world that the expedition is going to study their habits and customs in the hope of getting some light on health problems.

Better Supervision of United States Hospitals Needed.—Director Forbes of the War Veterans' Bureau has completed an inspection of all the principal Government hospitals in the United States. He is convinced that more rigid supervision of the hospitals is essential in the interest of disabled former service men, who are not getting a maximum of attention and treatment. Director Forbes claims that his survey disclosed that probably 60 per cent. of the number of former service men being treated in the hospitals established and maintained by the Government since the close of the

war are ambulatory patients, and are not in need of hospital beds. He finds that a heavy percentage of them have minor ailments.

Reception at the Lutheran Hospital.—The new extension of the Lutheran Hospital of Manhattan, situated at Convent Avenue and 144th Street, will be open for inspection to the members of the medical profession on Thursday afternoon, October 13, 1921, from 2 to 6 P. M.

Hospital Notes.—A campaign to raise $1,000,000 for the Greater Bikur Cholim Hospital, Brooklyn, has been started. Dr. George I. Miller is acting as chairman of the building fund committee.

The Harrisburg Hospital, Harrisburg, Pa., is endeavoring to raise a $900,000 building fund with which to provide hospital facilities to meet the growing demands of that city.

Plans have been formulated for the new Memorial Hospital to be erected at a cost of from $50,000 to $100,000 at Ventnor, near Atlantic City, N. J.

The contract has been awarded for the remodeling of Ward I of the Boston City Hospital, at an estimated cost of $15,000.

Plans have been completed for the erection of a $175,000 hospital for Leominster, Mass. Construction work will be begun immediately.

Health Week in Montclair.—The present week beginning October 3 has been set aside as Health Promotion Week in Montclair, N. J. Circus tents are being used for exhibits, lectures and entertainments. Twenty-three organizations are cooperating to make the project a success.

New York Death Rate Cut Again.—The record for the lowest death rate made by New York City during the week ending September 17 last was passed in the week ending September 24. The mortality rate for the latter week was 8.70, as compared with 8.77 for the preceding week. According to the records of the Health Department the death rate from January 1 to September 24 was but 11.40 for each 1000 inhabitants. If this rate should continue for the remainder of the year it will be the lowest annual death rate recorded since complete vital statistics for the city were instituted.

Serbian Physicians Visit United States.—A commission of three Serbian physicians, Dr. Georges J. Nikolitch, representing the Serbian Ministry of Health, and Dr. Georges Joannovitch and Dr. Radenko Stankovic, representing the Medical School of the University of Belgrade, have arrived in New York to study public health administration, medical education and hospital organization as guests of the Rockefeller Foundation. They expect to visit many cities in the United States and Canada for the purpose of gaining information which will aid in the promotion of public health programs and the development of medical education in Serbia.

The Eye Sight Conservation Council of America has been incorporated with headquarters in the Times Building, New York. The objects of the organization are to promote the general conservation and betterment of vision by arousing public interest to a proper appreciation of eye hygiene, especially in so far as it pertains to defective vision and protection in hazardous occupations; by circulating information on the proper lighting of homes, schools, factories, and all private and public buildings; by striving to bring about universal eye examination of industrial workers and school children, and also by urging the importance of periodical eye examinations for every one; developing and improving optical aids for the alleviation of visual troubles; compiling reliable data, publishing and circulating literature pertaining to eye care, and cooperating with all existing agencies concerned in any degree with the movement for better vision. Any person interested in the purpose of the organization is eligible to membership. L. W. Wallace of Washington, D. C., president of the American Society of Industrial Engineers, is president, and Dr. Cassius D. Wescott of Chicago, Ill., is vice-president.

College of Physicians and Surgeons of Columbia University Opens.—At the opening exercises of the College of Physicians and Surgeons on September 28, President Nicholas Murray Butler outlined plans for the upbuilding of the $15,000,000 medical center made possible by a permanent alliance between Columbia University and the Presbyterian Hospital and which begins a new era in medical education. Dr. Walter W. Palmer, who has succeeded Dr. Warfield T. Longcope as Bard professor of the practice of medicine, delivered the main address on "The Trend and Scope of Modern Medical Education." He referred to the controversies arising from the establishment of clinical branches on a university basis, and expressed the belief that this trend of medical education is in the right direction. Dr. Palmer closed with a prediction that new methods of obtaining degrees would result. "The time is coming when the better medical schools will so adjust their curricula as to make it possible for students to pursue their studies in such a manner that they may be enabled to present themselves for a degree when they themselves feel prepared. More latitude in moving from school to school will be possible. In this way the fundamental training so essential to good medicine will be better and more general. The wide variation in the several abilities of students will be met by this adjustment. The submerged will be given more time to emerge or left to their fate, and greater honors will come to honor men."

Gifts and Bequests.—The will of Mrs. Bertha Achelis makes bequests of $25,000 to the Lenox Hill Hospital, New York, and $5000 to the Monmouth Memorial Hospital, Spring Lake, N. J.

Bequests of $10,000 each are made under the will of Mrs. Mary Galvin Reynolds to the Seton Hospital, Spuyten Duyvil; Columbus Hospital, New York City; the Society for the Relief of Incurable Cancer, Hawthorne, N. Y., and St. Joseph's Hospital, Bronx.

Dr. Howard Fox has removed his office to 114 East Fifty-fourth Street, New York City.

Dr. Russell F. Maddren of Brooklyn, N. Y., recently sailed for China to occupy the chair of ophthalmology in the Yale Medical School at Changsha in the Province of Hunan.

Dr. W. Estell Lee of Philadelphia has been appointed a member of the Pennsylvania State Board of Medical Education and Licensure to succeed Dr. John M. Baldy, recently appointed Commissioner of Welfare. Dr. W. M. Hillegas of Philadelphia has also been appointed a member of the board.

Dr. E. B. Jermyn of Scranton has been reap-

pointed trustee of the Fairview (Pa.) State Hospital.

Dr. William F. Kuhn of Kansas City, Mo., was elected grand high priest of the general grand chapter of the Royal Arch Masons of the United States at its thirty-eighth triennial convocation held recently in Asheville, N. C.

Dr. F. S. White of Terrell has been appointed superintendent of the State Hospital for the Insane at Wichita Falls, Texas.

Dr. Harry M. Archer, Honorary Department Chief of the New York Fire Department, was recently presented with a gold watch and chain, a replica of his fire badge, and an embossed testimonial script in recognition of his surgical and medical work in the interest of the men in the department.

Vaccination Ordered for All Residents of Santiago de Chile.—The Chilean Government has ordered the immediate vaccination by the Army Medical Corps, the Red Cross assisting, of all residents of Santiago, because of the alarming increase of smallpox. It is estimated that there are more than 1500 cases in the city, with 700 in the pest house. The death rate is said to be low. The disease is reported to be on the increase in the interior towns, while at Valparaiso an average of seven new cases is reported daily. The railway companies have been instructed to refuse transportation to persons who cannot present vaccination certificates.

Shriners Plan Hospitals.—At a meeting of the Hospital Committee of the Imperial Council of the Shrine in St. Louis, Mo., September 25, authority was given to launch a campaign to raise $8,000,000 for hospitals. It is planned to erect a central hospital in St. Louis, to cost approximately $1,000,000, with subsidiary hospitals in San Francisco, Shreveport, La.; Portland, Ore.; Minneapolis or St. Paul, and Montreal, Canada.

Sanatorium Burns.—The Hilbourne Club, a sanatorium conducted by Dr. S. T. Armstrong near Katonah, N. Y., was totally destroyed by fire on September 26. The damage is estimated at $60,000.

Medical Society Elections.—The New England Surgical Society, at its fourth annual meeting held in Worcester, Mass., September 22, 1921, elected the following officers for the ensuing year: *President*, Dr. Charles A. Porter, Boston; *Vice-President*, Dr. Herbert L. Smith, Nashua, N. H.; *Secretary*, Dr. Philemon E. Truesdale, Fall River, Mass.; *Treasurer*, Dr. Peter P. Johnson, Beverly, Mass.

The Second Councillor Medical District Society of Ohio, at its annual meeting held in Dayton, September 19-23, 1921, elected the following officers for the ensuing year: *President*, Dr. C. I. Stephen, Ansonia; *Secretary*, Dr. D. B. Conklin, Dayton; *Treasurer*, Dr. H. C. Haning, Dayton.

Obituary Notes.—Dr. Sidney Wallace Dodge of Massena, N. Y., a graduate of the University of Vermont Medical College in 1875, died after a lingering illness on September 22, at the age of seventy-six years.

Dr. Matthew H. Cryer, formerly of Philadelphia, Pa., died at Lansdowne, Pa., on August 12, at the age of eighty-two years. He was graduated from the University of Pennsylvania School of Medicine in 1877. He was for many years professor of oral surgery in his alma mater, subsequently becoming emeritus professor. He was a member of the American Medical Association, the Medical Society Pennsylvania, and the Philadelphhia County Medical Society.

Dr. Timothy O'Rouke, a graduate of the Medico-Chirurgical College, Philadelphia, in 1911, where, for five years he was chief resident physician, died at his home in Philadelphia on September 6, at the age of thirty-six years.

Dr. Eliza O'Brien, a graduate of the Independent Medical College, New York, died in Utica, N. Y., on September 11, at the age of seventy-nine years. She formerly directed sanatoriums in Leadville, Salida and Denver, Col.

Dr. Flavius J. Groner of Grand Rapids, Mich., a graduate of the University of Michigan Medical School in 1880, died on September 14, at the age of seventy-two years.

Dr. Marian A. Dale of Mount Vernon, N. Y., a graduate of the New York Medical College and Hospital for Women in 1884, died on September 17, at the age of seventy-two years.

Dr. Charles B. Hopkins of Kansas City, Mo., died in Los Angeles, Cal., on September 13, from the effects of having been gassed in the World War. He was a graduate of Rush Medical College in 1900, and was a captain in the Army Medical Corps, taking part in the Argonne and St. Mihiel actions. Dr. Hopkins was forty-five years of age.

Dr. Ivan F. Siekmann of New Orleans, a graduate of Tulane University School of Medicine in 1892, died on September 10, at the age of fifty-nine years.

Dr. John W. Warren of Snyder, Texas, a graduate of the Kentucky School of Medicine in 1891, died on September 8, at the age of sixty-four years.

Dr. James A. Stafford of Newcastle, Ind., died as the result of a stroke of apoplexy on September 12, at the age of eighty-one years. He was a graduate of the Physio-Medical Institute, Cincinnati, in 1867.

Dr. Thomas Chalmers Johnson of Florence, S. C., died from heart disease on September 17, at the age of forty-three years. He was graduated from the Medical College of the State of South Carolina in 1904.

Dr. Robert H. Mason of Rochester, N. Y., a graduate of McGill University School of Medicine and Surgery in 1896, died September 23, at the age of fifty-two years. He was a member of the staff of the Park Avenue Hospital.

Dr. Sarah Perry of Rochester, N. Y., a graduate of the University of Buffalo Department of Medicine in 1882, died on September 9, at the age of seventy-four years.

Dr. William J. Conklin of Beacon, N. Y., a graduate of New York University Medical College in 1870, died of heart disease on September 27, at the age of seventy-five years.

Dr. Charles H. Smith, a graduate of Hahnemann Hospital and Medical College, Philadelphia, in 1876, died at his home in that city on September 20, at the age of sixty-seven years.

Dr. Thomas J. Battle, a graduate of Bellevue Hospital Medical College in 1897, died at his home in New York on September 28, at the age of fifty years.

Correspondence.

BACTERICIDAL ACTION OF HEAT IN GONORRHEA.

To the Editor of the Medical Record:

Sir:—Apropos to the extract in the Medical Record from the *Wiener klinische Wochenschrift* and the letter of Dr. P. H. Anderson in the Medical Record of July 30, the following two cases corroborate the assertion that fevers destroy the gonococcus.

Case I.—A medical friend called to see me on July 13, 1920; he was in a very excited state, for he had seen some viscid pus about the meatus urinarius; he remembered that for a few days previously, he had felt some burning on urination, and he had also observed that his underclothes were soiled for the few preceding days. On examination, the meatus was seen to be red and angry-looking with a purulent discharge; a specimen was sent to a bacteriologist who found gonococci in abundance. He treated himself with all sorts of injections and internal medication with no perceptible amelioration. On the 25th of the same month, he came down with a fever; his temperature was 38° C.; the case was diagnosed as dengue; on the following day the temperature rose to 39° C. I gave him antipyrin and aconite in combination; on July 27 the temperature fell to normal. With the subsidence of the fever, the gonorrhea was found to be cured.

Case II.—On April 26, 1921, I. K. presented himself for treatment; he suffered severe burning on urination; there was an abundant purulent discharge from the urethra; the meatus was red and inflamed; on milking the urethra, pus flowed out in plenty; the pus was sticky and of a greyish yellow tint; his temperature was 37° C.; the bacteriological examination confirmed the diagnosis of gonorrhea. The discharge did not abate in spite of the permanganate and other injections. On the 30th of the same month, the man came down with fever, the temperature being 39° C. From the symptomatology, the course of the disease, and the bacteriological examination of the blood, relapsing fever was diagnosed. In addition to the treatment of the second disease which lasted till the 23d of last May, injections of potassium permanganate were continued till May 2, 1921, when the gonorrhea was cured; since then the relapsing fever has never reappeared.

From the cases mentioned in the Medical Record and from my two cases (surely the cure of the last case was not due to the permanganate injections), one is bound to conclude that fevers destroy the gonococcus. Whether this killing of the gonococcus is solely due to the heat accompanying the fever or to the toxin generated by another microbe, is difficult to determine at this juncture; more research and time are required; probably both agents cooperate, with the toxin playing the preponderant part. However, it is well worth the trouble to try artificial heat locally in the treatment of gonorrhea; the applied heat should not be lower than 39° C. (102.2° F.).

H. T. M. K. Rahmet Bey, M.D.

141, Rue Abbas, Cairo, Egypt.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, September 15, 1921.

Meeting of the British Association in Edinburgh.—The meeting of the British Association for the Advancement of Science opened in Edinburgh on Sept. 7, last, under the presidency of Sir Edward Thorpe. This was the eighty-ninth annual meeting of the association, which had not met in Edinburgh for a period of twenty-nine years. There were many questions of a medical scientific interest dealt with.

Vocational Training and Tests.—On Sept. 8, when the real work of the Congress commenced, vocational training and tests was one of the most important subjects to which attention was directed at a joint meeting of the Economic, Psychological, and Educational Sections. Dr. C. W. Kimmins, who introduced the subject before a large audience, spoke of the number of children who, on leaving school, found themselves in occupations for which they were unsuitable. The state of affairs in this respect in London was really tragic. Children drifted from one kind of work to another, and in many cases boys of great promise became van boys. Since psychologists had taken an important part in the investigation of children it was noticed that a great change had been brought about. The intelligence test to a certain extent was being used in connection with the transference of children from one class to another in the elementary and, in some cases, the secondary schools. That was a very important matter because it gave them a much better knowledge of the child. In an East-end of London school, where the old conditions were absolutely unfavorable, there was a singularly able headmistress, who had made a close study of intelligence tests and, on receiving children from the infants' department up to the senior departments, tested each child to find out what its natural ability was. She had previously had the record of its educational achievements from the infants' school, and, using this as a basis of classification, the whole aspect of the school had changed, and had now entered the scholarship-winning list without placing any burden upon the child in the form of extra work. This change had been brought about by arranging a system by which it could be shown what a child was best fitted for on leaving school. They were looking forward to the time in London when they would have a record in regard to every school child, so that they should be able to avoid so many of the misfits that were now to be seen. Mr. D. Kennedy Fraser, Scottish Education Department, expressed his belief that vocational training would play an important part in any properly organized system of education. He mentioned that in the United States Army during the war about 45,000 recruits, or one man in forty, did not surpass the normal level of a normal child of ten years. He suggested that all children should be given some form of general intelligence test and be classified into normal, bright, and backward, and that the backward should receive a vocational education in which they might be successful later on.

Autosuggestion in Shell-shock.—On Sept. 9, in the Section of Psychology, psychoanalysis and suggestion were discussed by Dr. W. Brown of London. He remarked that a very large number of symptoms of shell-shock could be explained in terms of bad autosuggestion. For instance, a patient lost his voice under the influence of emotional strain and became mute, or, again, a patient lost the power of walking. In one case a soldier was guarding a munition dump when it was blown up by a bomb from an aeroplane. He ran away in a state of intense fear, felt that the muscles of his leg refused to act, and fell down. The idea crossed his mind that he was paralyzed; consequently he became really paralyzed. The symptom had been produced by bad autosuggestion. The cure was to suggest to him and persuade him that he could walk. Such cases, when so treated in their early stages, were permanently cured. There were patients going about paralyzed who should have been cured years ago.

The Instinct of Acquisition.—On Sept. 12, in the Section of Psychology, Dr. W. H. R. Rivers of Cambridge read a paper on this subject. He said, in part, that it had become widely recognized that the behavior of mankind was determined, to some extent, by inborn factors or tendencies, and it was accepted equally widely that it was only very rarely that human behavior was purely instinctive. He pointed to the evidence of instinct in birds and animals, and, coming to man, he said that the leading feature of many forms of insanity was an impulse to collect, apparently with little or no regard to the nature or value of the objects collected. As for the question how far acquisition by the individual could be held to have an instinctive basis, it was possible that different branches of mankind might have been separated for a sufficiently long period to have undergone development on different lines and become endowed with different instincts, but it was far more probable that the instinctive equipment of all the human species was alike and that any differences were due to the different degrees in which the common instinct had suffered modification in the individual as the result of tradition and social environment.

The Sense of Humor in School Children.—On Sept. 13, in the same section, Dr. C. W. Kimmins of London, who has carried out recently an investigation of the sense of humor in school children, gave some of the results of his inquiries. Doctor Kimmins said that among the many interesting facts deduced from his investigations he noticed the extraordinary appeal of Charlie Chaplin to young children. The reason for that was because there was not only continual movement and change of action, but also that Chaplin was breaking all social conventions and doing the very things that children were forbidden to do. Doctor Kimmins went on to explain that his object in carrying out an investigation was to discover the measure of the material which, at different ages, caused amusement and provoked laughter. As to the chief causes of laughter, experts were not in agreement. Bergson maintained that the comic was that side of a person which revealed his likeness to a thing and conveyed the impression of pure mechanism. The corrective was laughter. Absent-mindedness he described as one of the great watersheds of laughter, and said it was the part of laughter to reprove absent-mindedness. Freud in his "Wit and the Unconscious" had elaborated the idea of pleasure being derived from the economy of psychic expenditure. Word pleasure and pleasure in nonsense, Freud said, were a relief from critical reasoning. Man was an untiring pleasure-seeker. Under the influence of alcohol a man became a child again and was freed from logical inhibition. Sidis held that laughter never came from economy, but from superabundance of energy. Another authority declared that laughter bound us to the childhood of the race. There was no difference of opinion as to the physiological value of laughter. Doctor Kimmins said that cases of puns perpetrated by children under seven years of age were rare, while many of the reported stories were due to misunderstanding of the words used. As an illustration he quoted the classic instance reported by Sir Joshua Fitch, who asked some small children to write the Lord's Prayer and afterward came across such mistakes as "Harold be Thy name," "Lead us not into Thames Station." The records of children of nine years of age showed a very great change. Boys and girls at this period were particularly interested in funny stories and jokes; riddles and play upon words maintained their position at that age, but the popularity of the misfortunes of others as a source of merriment was ceasing to exist and soon disappeared entirely. At ten years of age children were very keen on books of jokes and comic papers. The affairs of the classroom were found to afford suitable material for the gratification of the sense of humor. The period between eleven and thirteen years of age appeared to mark quite clearly the parting of the ways, and a sense of humor seemed to disappear entirely. The funny story was of a far more personal nature, the element of superiority ran riot, and children delighted in extravagant stories of stupidity concerned with adults. Stories involving a smart but often rude retort appealed at this age, and to illustrate this point the speaker mentioned the teacher who told a small boy that when Lloyd George was at his age he was head of the school, to which the boy replied that when Lloyd George was the teacher's age he was Prime Minister. In the period from fourteen to fifteen years of age it was more difficult to generalize. There appeared to be, however, very clear evidence that the revival of humor at thirteen, in the case of girls, and fourteen, in the case of boys, was well maintained. Doctor Kimmins concluded by saying that the opinion was held by many educators that it was possible to increase the sense of humor in the ordinary intelligent child, and experiments had been carried out which, it was claimed, had been crowned with success. The subject was worthy of further investigation. A keen sense of humor was a valuable possession and added much to the joy of life. Laughter was a great relaxation from the conventions of every-day life, and if the springs of laughter were pure they should be encouraged.

The Psychological Treatment of the Delinquent

Child.—In the same section, on the same day, Dr. A. R. Abelson, London, advanced reasons for the psychological treatment of the delinquent child. He said there was an accumulating amount of reliable evidence that wrongdoing was largely bound up with morbid conditions of health. The method of dealing with the delinquent child in Great Britain, though much improved, was far from satisfactory. Was it really necessary, he asked to degrade a child first in order to reform him? Many a child looked upon his incarceration in an institution as a malignant stain on his soul which could never be effaced and would go down with him to the grave. Some of these children had high ideals, but there was always to be found in such cases a severe mental conflict, which could only be satisfactorily removed by psychological analysis. There was frequently associated endocrine disturbance, and much could be done in some cases by associating remedial measures with psychological treatment. It was time we seriously realized that we were dealing, in the large majority of cases, with a pathological condition which, like all pathological conditions, required adequate treatment. He ventured to assert that delinquency in cases where there were no gross mental abnormalities was curable, and this was more than could be said for a large number of generally accepted medical diseases; yet the erring childhood up to the present time received most inadequate attention from the treatment point of view. Prof. C. S. Sherrington, president of the Royal Society, has been appointed president of next year's meeting of the British Association, to be held at Hull. More than 2,500 members attended the meeting this year. This eclipses last year's total of 1,400 at Cardiff, but is by no means a record, for at Birmingham, in the eighties, nearly 4,000 registered.

Progress of Medical Science.

Boston Medical and Surgical Journal.

September 22, 1921, clxxxv, 12.

1. Nomographic Charts for the Calculation of the Metabolic Rate by the Gasometer Method. Walter M. Boothby and Raymond B. Sandiford.
2. The Hospital as a Diagnostic Center. Ernest L. Hunt.
3. The Resident Surgeon and the Hospital. Donald S. Adams.
4. Extrapleural Resection and Plastic of the Thoracic Esophagus. An Original Method. Report of a Successful Case Without Gastrostomy. Howard Lilienthal.

1. Nomographic Charts for the Calculation of the Metabolic Rate by the Gasometer Method.—Walter M. Boothby and Raymond B. Sandiford state that for the estimation of the basal metabolic rate there are only two types of apparatus, the accuracy of which has been sufficiently controlled up to the present time by scientific experimentation to justify their consideration for clinical work. These are the Benedict closed-circuit system, and the open-circuit system, known as the Tissot or the gasometer method. Either type of apparatus, when properly constructed and properly run, will give accurate results. For the past four years the writers have been using the gasometer method for various reasons which they discuss in detail. While not wishing to minimize the difficulty of gas analysis, they believe that these have been magnified and do not outweigh the advantages of the gasometer method. The tables for the calculation of the metabolic rate which Boothby and Sandiford have published have been condensed without loss of accuracy, so that the metabolic rate can be calculated by a graphic method in less than five minutes. An abridged logarithmic factor table for reducing gas volumes to standard temperature and dry pressure is also included, so that, if preferred, the calculation may be carried out first by logarithms and the result checked by the graphic charts. For this purpose a "calculation form" adapted for rapid checking of each step of the mathematical calculation by the charts is arranged. The method of construction of these charts is given in order to aid those who may desire to construct similar charts to solve a frequently used equation in their own work. The writers again emphasize, as they have many times before, that the basal metabolic rate will fall into great discredit and the entire question of variation in the rates in various diseases be utterly confused by careless and improper technique in their determination.

1. Pseudotabetics and Their Reeducational Treatment.—Pierre Kouindjy states that psuedotabes is not as rare as has been assumed. It may be due to a number of different causes, such as intoxication, infection, and overwork; it may also have a syphilitic origin. The symptoms recall those of true tabes dorsalis. In spite of this, pseudotabes is a pathological entity easily distinguished from true tabes on account of its etiology and, especially, of its course. Pseudotabes is characterized by its tendency to complete cure, by tenderness on pressure of muscles, by the absence of the Argyll-Robertson pupil, by the different topographical distribution of anesthesias "which here diminish from the distal end toward the root of the limb, whereas in tabes they always show a radicular distribution." The pains in pseudotabes differ in character from the lightning pains of true tabes. They seldom occur in the form of true crises, and often they are only of short duration. Two causes are necessary for the production of pseudotabes: (1) The true etiological cause, such as intoxication or infection, and (2) the predisposing cause—the psychic condition of the patient. Pseudotabetics are above all neurotics. This fact serves to explain the rapid development of the illness as well as the complete cure and the disappearance of symptoms. The treatment of election of pseudotabes must comprise treatment of the etiological cause and also symptomatic treatment. Physiotherapeutic treatment occupies a prominent place in the second instance. Reeducation of movements forms the pivot of the kinetic treatment of pseudotabes, being calculated to combat at the same time both the motor disturbances of progression and the psychic state of pseudotabetics.

5. Endobronchial Treatment of Bronchial Asthma and Asthmatic Bronchitis.—Mark J. Gottlieb claims that endobronchial treatment is the most valuable procedure that we have at our disposal for treating cases of asthmatic bronchitis and bronchial asthma, where elimination of the allergic substances and vaccine therapy, combined with other measures suggested, have failed to produce the results desired. Astringents, such as silver nitrate and tannic acid, have not only the property of temporarily dilating the lumen of the bronchial tree, but also, when applied often enough, say weekly, have the effect of rendering the mucous membrane less susceptible to infection. Factors usually not considered

in the etiology of bronchial asthma, which are important, are susceptibility of the bronchial mucous membrane to reinfection, habit, and psychology of the patient. Vaccines of the predominating organisms found in the sputum or nasal discharge are of value, especially in those cases in which the individual is sensitive to autogenous suspensions of these, with the exception of *Bacillus influenzæ*. Vaccines of *B. influenzæ* in the writer's cases had not the slightest effect in ameliorating the symptoms.

7. **A Few Meteorotelluric Observations.**—From a study of 1184 cases of summer autumnal coryza and asthma extending over a period of twenty-five years, George N. Jack concludes that heat, or a temperature above 86° Fahr., in an arid atmosphere does not as a rule cause heat retention hemolytic crises, or heat prostration, owing to the rapid elimination of end metabolic products through perspiration and evaporation. Heat, or a temperature above 86°, in a humid atmosphere or humidity above 70°, often results in heat retention hemolytic crises, as heat prostration, sunstroke, and dropsy, and when a spell of weather of this character is followed chilly, humid, dewey, ground gas accumulating, blood disintegrating nights with a temperature below 60° or between 34° and 60°, then after the blood disintegrates it dumps its disintegrated material through an exudative process that results in summer autumnal coryza, asthma, eczema, cholera infantum, cholera morbus, dysentery, or vomiting, according to the line of least resistance.

14. **Abdominal Contraction Method of Diagnosis.**—L. Winfield Kohn does not claim that this method which he describes is altogether adequate. He says that the *x*-ray and other studies give more definite information, yet for a simple method, easily induced with no discomfort to the patient, it is productive of information that is often of value. The method is based upon the principle of increased intraabdominal tension, and the pressure is directed in a downward direction. The patient is instructed while in the recumbent position to take a deep breath and then bear down upon the abdomen while holding the breath. As a result the diaphragm is prevented from moving upward by the closure of the glottis and the abdominal muscles are contracted down while the muscles of the perineum are relaxed, in consequence of which the visceral organs of the pelvis are forced downward. During this act the stomach and bowels assume a more anterior as well as lower position in the abdomen and are, therefore, more accessible for study. Inspection, percussion, auscultation, deep pressure, and other palpatory methods, may be practised while the abdomen is thus contracted. This method will serve to demonstrate weakness in the abdominal wall, such as ventral and inguinal hernias, diastasis recti, general abdominal loss of tone, and similar conditions. Visceroptosis will appear more clearly defined in many patients, especially fat people, who do not ordinarily show this condition. A ptotic kidney or liver that was impossible of palpation through other means may be revealed by this method. Abdominovaginal or abdominorectal palpation during the application of this method will also facilitate the examination of the Fallopian tubes, ovaries, and uterus. In acute diseases of the abdomen, where muscle rigidity over the diseased organ has already established itself, this superadded contraction effort seems to aggravate the existent tenderness or pain.

4. **A New Roentgen-Ray Sign of Ulcerating Gastric Cancer.**—Russell D. Carman, while admitting that an attempt at roentgenological differential diagnosis of those benign and malignant ulcers which cannot be distinguished macroscopically seems futile, says there are well-defined ulcerating gastric cancers which are probably malignant from the beginning. The pathologist is able to recognize them as carcinomas grossly by their elevated irregular overhanging margins; their ragged floors covered with mucilaginous exudate, and their tendency not to perforate although they may involve the serosa. The roentgenologic appearance of this type of malignant ulcer is so definite that it may be considered pathognomonic. Fluoroscopic examination is essential for the routine demonstration of this lesion. The details of examination and the appearance of the ulcer vary slightly, depending on the site of the lesion. When the ulcer is on the vertical portion of the lesser curvature, approximation of the walls of the stomach by palpation causes a dark, slightly crescentic shadow of the barium-filled crater to appear on the screen. In these situations the convexity of the crescent is toward the gastric wall and the concavity toward the gastric lumen. If the ulcer saddles the lesser curvature distal to the incisura angularis of a fishhook stomach a meniscus is similarly revealed by palpation, but in this instance the base of the ulcer follows the bending line of the curvature and the concavity of the meniscus is toward the gastric wall. When the ulcer is on the posterior wall, well away from the curvature, thinning the barium by stroking pressure with the hand reveals the crater as a somewhat circular, dark shadow surrounded by a lighter zone. If the ulcer is on the posterior wall and its crater can be demonstrated in the anteroposterior view, but no niche can be seen in the oblique view, one may believe he is dealing with this particular type of malignant ulcer. In fact, the absence of a classic projecting niche is one of its principal differentiating characteristics. Another differential point between this type of malignant ulcer and a simple ulcer is that in the former the barium is dislodged from the crater with difficulty, while in the latter the barium is easily emptied because it has no overhanging margins. The findings described are limited to malignant ulcers ranging from 3 to 8 cm. or more in diameter, with relatively deep craters.

8. **Squint: When Shall We Operate?**—A. S. Green and L. D. Green call attention to the lack of specific indications for operation in squint such as are given for glaucoma or cataract in text-books and other medical literature. According to their observations, based on a careful study of 260 private cases, less than 25 per cent. of squinting eyes that come to the ophthalmologist are improved by nonsurgical methods. Thus over 75 per cent. of these patients are left to be corrected by operation or the alternative of going for the rest of their lives with the deformity. The small proportion of patients amenable to nonoperative means is no doubt due to the fact that less than 50 per cent. of the patients were under eight years of age. Great harm has undoubtedly resulted from the advice so frequently given by physicians to parents to wait until puberty to see whether the child will outgrow the squint. When the nonoperative treatment is to be instituted it must be begun before the age of eight or before commencing school if any degree of success is expected. Two hundred and thirty-five answers to a questionnaire sent to ophthalmologists leads to the conclusion that few ophthalmologists have a well-defined procedure for handling a case of squint, and that there is a general tendency to delay operation later than is advisable. It is of vital importance that the family physician and the public be impressed with the necessity that the child have early attention. Operation should be performed in all cases in which there is no reduction in the squint under complete cycloplegia, irrespective of the age of the patient.

10. Cultures Smears and Guinea-Pig Inoculations in Diagnosis of Renal Tuberculosis.—Abraham Hyman and Lewis T. Mann, on the basis of their observations and experimental work, assert that the presence of tubercle bacilli in the catheterized bladder or ureteral specimen of urine does not necessarily imply a renal tuberculosis. Tubercle bacilli may be present in catheterized ureteral specimens under three conditions: (1) When there is a tuberculous focus in some part of the body and the bacilli are excreted from a non-tuberculous kidney; (2) when there is a tuberculous focus in the genital or urinary tract by contamination or by ureteral reflux, and (3) when the tuberculosis is in the upper urinary tract or kidney. Kidneys the seat of disease other than tuberculosis (stone, tumor, nephritis) more readily allow the passage of tubercle bacilli than normal organs. In summing up the relative advantages and disadvantages of the smear versus guinea-pig inoculation, the writers have found the smear a simple and rapid procedure, which gave them positive results in 65 per cent. of the cases, and for these reasons was of greater value than inoculations. The guinea-pig test is so time consuming as to render it impracticable as a routine procedure. The diagnosis in this series was in most instances made on a careful study of the clinical symptoms, cystoscopy, and smear examinations. Animal inoculation should be resorted to when the smear proves negative, and when there is a question as to the involvement of the opposite kidney. Occasionally the pig will pick up an unsuspected case of renal tuberculosis which could not have been detected by other means.

11. Therapeutic Value of Chaulmoogra Oil and Its Derivatives in Experimental Tuberculosis.—Carl Voegtlin, M. I. Smith, and J. M. Johnson report an exhaustive experimental test of the value of chaulmoogra oil and its derivatives in various stages of experimental tuberculosis in the guinea-pig. They are not able to show that the treatment had any favorable action whatsoever. The mortality curves of the animals treated are somewhat more steep than of those untreated, which may possibly indicate that the treatment had a deleterious effect. An iodine preparation was used because Jobling and Peterson have shown that iodine has an inhibiting effect on the antiproteolytic ferments in the blood, and it was thought that through its indirect action it might render the tubercle bacilli in the lesions more accessible to the drug, and in one group the animals were treated with ethyl esters before and after infection. Even this intensive treatment had no effect on the course of the disease.

12. The Gram Stain in the Diagnosis of Chronic Gonorrhea.—Victor Burke finds that the addition of sodium bicarbonate increases the value of the Gram stain as an aid in the diagnosis of chronic gonoccal infection. It does this in two ways: (*a*) It results in a heavier concentration of the violet dye remaining in the Gram-positive organisms. (*b*) It causes some of the Gram-positive organisms which would otherwise appear negative to retain the violet dye. The addition of lactic acid interferes with the Gram reaction. The sodium bicarbonate probably affects the Gram reaction by increasing the penetration and concentration of the dye within the cell rather than by any action on the cell wall or the molecules of the dye-iodin precipitate. The effect of sodium bicarbonate and lactic acid on the Gram stain suggests that some of the difficulty experienced in making a satisfactory Gram stain on smears from the genitourinary tract is due to the presence of acid in the secretion.

2. The After-Effects of Epidemic Encephalitis in Children.—Donald Paterson and J. C. Spence have observed the after effects of epidemic encephalitis in twenty-five children between the ages of three months and eleven years. They believe that we may expect to find various degrees of permanent disability in many of the patients who have had this disease, which may affect either the mental or the physical condition. In this series of cases only one-fourth made a complete recovery. The mortality rate in this disease in children is low; 1 in 25 in the present series. The results of the mental changes following encephalitis in childhood may vary from complete idiocy to slight mental deficiency. They may also show themselves as affections of the character and habits of the child. The physical changes following encephalitis in childhood include spastic diplegia, hemiplegia, symptomatic paralysis agitans, muscular rigidity, and tremors. The younger the child at the onset of the disease, and the longer the acute stage of the illness, the greater will be the degree of mental deficiency which follows it. The severity of the initial attack of encephalitis appears to be in direct proportion to the after-results which follow it. This suggests that could some means of treatment be found which would limit the progress of the disease or shorten its course, the results would not be as drastic as they now are.

3. Effect of Culture Media upon Agglutination of Meningococci.—I. Walker Hall and G. E. Tilsley summarize their experimental work concerning the growth of meningococci in various media, in which the technique was modeled as far as possible upon the criteria demanded by Tulloch, as follows: (1) Variations in culture media are associated with changes in the agglutinability of organisms. Individual strains of meningococci when grown on nut nasgar media become more agglutinable than when they are grown on legumen agar, with or without the addition of blood. This observation may be a possible explanation of some of the "inagglutinable" strains of various bacteria. (2) The agglutinogenic substance in meningococci shows also a relation to the content of nutrient media. It is more active in coccal emulsions prepared from nut nasgar media than those obtained from legumen media. This may have a bearing upon the production of antiserums. (3) Emulsions of meningococci in normal saline made with freshly distilled water heated to 65° C. for 20 minutes, standardized numerically, and then preserved with 0.5 per cent. phenol, have remained unchanged as to numbers, and sterile for five years. At the end of this period the agglutinability and agglutinogenetic capacity persist practically unaltered.

5. The Value of the Complement Fixation Test in Tuberculosis.—A. Lisle Punch has tested 185 bloods in the laboratories of the Institute of Pathology and Research at St. Mary's Hospital, according to the method published in *The Lancet* of September, 1920. The results in this series are strictly comparable to those obtained in the series previously published, and the conclusions drawn from the previous results are confirmed by the present series, namely: (1) That in the complement-fixation test we have a reliable means for the diagnosis of an active tuberculous lesion (pulmonary). The pulmonary form only is dealt with in this paper. (2) That a negative result is as reliable indication of the absence of such a lesion as a positive is of its presence. The writer has had similar results in another series of 450 cases at the Brompton Hospital, which are still unpublished.

4. Present Views on Anaphylaxis. Jules Bordet.

2. Pernicious Anemia. A Clinical Study of One Hundred and Fifty Cases with Special Reference to Gastric

Anacidity.—Samuel A. Levine and William S. Ladd found among their 150 cases of pernicious anemia seven in which the subsequent course of the disease indicated that the diagnosis was wrong or, at least, threw considerable doubt on its correctness. The gastric secretion in the fasting contents and after an Ewald test breakfast was analyzed in 107 of the 143 cases of pernicious anemia. Analyses were made repeatedly on the same patient when the blood condition was low and when it was normal, and some analyses extended over many years. In only three cases was hydrochloric acid found at any time in the gastric secretion, and in two of these cases the diagnosis of pernicious anemia was questioned. These figures then show a persistent anacidity in 99 per cent. of cases of pernicious anemia. Pepsin was tested for a small number of cases and was always found lacking. The evidence goes to show that the changes in the gastric secretion occur very early in the disease, often years before the blood picture develops, and that once established they are never altered by the remissions so characteristic of the disease. The presence of free hydrochloric acid in a suspected case of pernicious anemia is important evidence against this diagnosis. In five patients who showed varying amounts of free hydrochloric acid in the gastric secretion, operation, post-mortem examination, or subsequent findings practically ruled out pernicious anemia. Its absence should suggest pernicious anemia as a probable diagnosis worthy of consideration. A distinct familial incidence was discovered in studying these 143 cases. In nine patients there was a definite family history of pernicious anemia in some other member of the family. In two others there was a history of death from an unknown type of anemia. Forty-one had a family history of tuberculosis or cancer or of both, and as these diseases are easily confused with pernicious anemia, these figures may well include cases of anemia. There are racial discrepancies in the incidence of this disease. The figures studied would indicate that pernicious anemia is less frequent in the Italians, Russian Jews, and immigrants from Eastern Europe, than in Americans, Canadians, or immigrants from Ireland, England, Sweden, or Denmark. Syphilis apparently bore no relation to the development or course of pernicious anemia in this series. The presence of eosinophilia is a common finding in pernicious anemia. Of the 143 patients, 54 showed 5 per cent. or more at one time or another. Even a very high eosinophilia—25 per cent. or more—is not incompatible with the disease. In 76.9 per cent. of the cases the blood smear might be called typical of pernicious anemia, in 18.2 per cent. it was suggestive, and in 4.9 per cent. it was atypical or within normal limits. This is in striking contrast with the more constant finding of anacidity. Of 127 patients in whom the appearance of the tongue was described, in 63.8 per cent. it was typically smooth and atrophic, in 19.7 per cent. it was suggestive, and in 16.5 per cent. its appearance was about normal. The proportion of males to females in this series was as two to three. The average age of all patients of both sexes was about 51 years.

3. **Gland Puncture as a Diagnostic Measure.**—C. G. Guthrie states that although a valuable aid in diagnosis gland puncture has thus far been used only for the recognition of various etiological agents of disease, bacteria, protozoa, and filariæ. It seemed possible to the writer that the method might be applied to the study of other conditions by the recovery of cellular material for microscopical examination. For the puncture a 2 c.c. Record syringe is used, equipped with a 21-gauge needle, 5 cm. in length. The point of the needle has a sharp bevel and is sharpened each time just before sterilization. Under aseptic precautions the needle is inserted well into the gland. The syringe and needle are then rotated about their longitudinal axis and the plunger is drawn out to 1 c.c. to create suction. The needle is then slowly withdrawn, negative pressure being maintained throughout. Thus far this method of diagnosis has been applied in cases of syphilis, tuberculosis, Hodgkin's disease, acute and chronic lymphoid leucemia, acute and chronic myeloid leucemia, simple adenitis, and in one instance each of trypanosomiasis and of metastasis of malignant disease. A positive diagnosis dependent upon the recovery of the etiological agent was possible in a number of cases. The results obtained from the study of cellular material aspirated from glands is of particular interest. In Hodgkin's disease it has been possible to make a definite diagnosis in all of the cases examined thus far. The presence of eosinophiles, large endothelial cells, and the peculiar multinucleated giant cells gives a characteristic and usually unmistakable picture. In the cases of leucemia the gland picture has, to a remarkable degree, reflected the blood picture. It is possible that if the blood were in an aleucemic stage and recognition of the disease consequently more difficult puncture of a gland might yield information of considerable value in arriving at a diagnosis. In simple adenitis the picture is one of lymphoid hyperplasia, as is evidenced by the presence of large numbers of lymphoid cells in various stages of maturity, plus the presence of polymorphonuclear neutrophile leucocytes. The advantages of the method are the following: (1) Rapidity; not infrequently a definite diagnosis may be made in ten or fifteen minutes. (2) Thin preparations like blood films are secured, suitable for the application of a blood stain or special stains for cells, bacteria, or protozoa, and permitting the use of an oil immersion lens in their study. (3) The procedure is practically painless to the patient and leaves no scar. (4) It does not interfere with subsequent excision and histological study of the gland. The limitations of the method are that from a fibrotic gland very little cellular material may be recovered, sometimes not enough to enable one to make a diagnosis; the cellular picture obtained is necessarily that from a very limited area of the gland; the architecture of the gland is not shown as a rule, although occasionally a small bit of the gland is removed intact in the course of the puncture.

La Presse Médicale.

August 27, 1921, xxix, 69.

Mode of Origin of Pneumonia.—Marie first discusses the prevalent view of aerial transmission by germs from subjects or carriers, which organisms use the mouth as a sort of reservoir in which virulence is enhanced. The germ then travels along the air passages to the lobes of the lungs, and sets up a local general infection. Contending beliefs have it that the pneumococcus affects the lungs after intestinal absorption and by other extra-aerial routes. Generally speaking, there are the aerial and hematogenic theories with the intermediate view that the germ may gain the blood through the air passages without reference to the production of local lesions. According to this latter view, the initial lesions in the lungs may escape clinical observation at times. Some of these centrally located lobar pneumonias are brought to light by radioscopy. Positive hemoculture may also coexist with absence of positive clinical finds. According to the hematogenous theory the local alterations would be secondary, at least in a fraction of cases. Secondary pneumonia as a complication of a bacteriemia is a very common occurrence. The mere find of bacteriemia does not necessarily mean that the germs are virulent or that they produce the phenomenon of lobar pneumonia. The opposed views overlap to such an extent that experiment ought to be of crucial importance. It must be confessed that experiment favors the aerial theory to the extent that the insufflation of the germs into the bronchi seems to be able to set up the disease. If they are introduced into the nasopharynx and upper passages in general pneumonia does not develop. Once the germs are within the trachea and bronchi bacteriemia soon follows. As far as experimental pneumonia is concerned the local manifestations are primary, the blood state secondary. Conversely when virulent pneumococci are injected parenterally the animals die of sepsis without the formation of pulmonary lesions.

Failure of Anticocaine Legislation in Paris.—Courtois-Suffit and Giroux announce that the present laws against the sale of cocaine are ineffective. These went into effect in 1916, but immediately after the armistice the drug began to cross the German frontier and from 1916-20 the convictions became threefold more numerous.—*Le Bulletin Médical.*

Book Reviews.

INJURIES AND DISEASES OF THE BONES AND JOINTS—THEIR DIFFERENTIAL DIAGNOSIS BY MEANS OF THE ROENTGEN RAYS. By FREDERICK H. BAETJER, M.D., Associate Professor of Roentgenology, Johns Hopkins University; Roentgenologist, Johns Hopkins Hospital, and CHARLES A. WATERS, M.D., Instructor in Roentgenology, Johns Hopkins University; Assistant Roentgenologist, Johns Hopkins Hospital. Illustrated with 332 roentgenograms and one line drawing. New York: Paul B. Hoeber, 1921.

BAETJER and Waters present in their introductory chapter a basic concept of *x*-ray pathology in which they state that the correctness of a diagnosis depends entirely upon the skill with which the various shadows projected upon the photographic plate are separated and interpreted; and that the correct interpretation is dependent upon not only the appearance of the normal structures but also upon the alterations that follow when pathology is present. Immediately follows a consideration of normal bones in which the several structures are analyzed and divided into periosteum, cortex, medullary canal, nutrient foramen, cartilage, joints, and the effect of sex and growth on the appearance of these structures. In the next chapter the epiphyses are especially studied, this portion of the bone playing an important part in growth and being easily affected by injury and disease.

Chapters IV to VI deal with fractures of the upper and lower extremities, under which topics the elements affecting fracture, such as muscular tension, age, sex, occupation, etc., are critically discussed.

Chapters VI and VII are devoted respectively to the consideration of congenital and acquired dislocations. Bone infections, particularly osteomyelitis, are next considered. This is followed by a review of joint lesions in children and in adults.

Chapter XI presents an excellent discussion of bone tumors in which a basis of classification is presented according to the origin, whether medullary or cortical; the presence or absence of bone production; the condition of the cortex, whether destroyed or expanded but intact; and, finally, the question of invasion. An excellent dictum is expounded: "Never make a diagnosis of tumor because it looks like something that has been seen before." It may be added that this postulate applies not only to the diagnosis of bone tumors but also to *x*-ray diagnosis in general.

A chapter is devoted to lesions of the spine; one to various abnormalities such as extra ribs, rudimentary vertebræ, etc.; and, finally, a chapter on dystrophies including Paget's disease, acromegaly, osteomalacia, and several bone and cartilaginous imperfections.

It is assumed that the roentgenologist is already familiar with *x*-ray technique; this granted, Baetjer and Waters' volume presents a remarkably lucid explanation of pathologic changes involving injuries and diseases of bones and joints. The illustrations are many and excellent.

THE PRINCIPLES OF IMMUNOLOGY. By HOWARD T. KARSNER, M.D., Professor of Pathology, Western Reserve University, Cleveland, and ENRIQUE E. ECKER, PH.D., Instructor in Immunology, Western Reserve University, Cleveland. Containing 309 pages and 20 illustrations. Philadelphia: J. B. Lippincott Company, 1921.

THE study of immunity has offered many opportunities for research and for observation. In recent years a vast amount of writings have accumulated, some confirming previously reported observations, others purporting denial of explanations of observed phenomena, and still others advancing presumably new facts. So that a book on immunology is, after all, primarily a compilation; and its value depends as much upon the careful selection of the subjects presented as it does on the manner in which they are presented. The authors expound the principles of immunology through a sequence that is at once logical and direct. They consider first the virulence of organisms. This is followed by a brief discussion of the general conditions of infection and resistance. Then the general phenomena of immunity are reviewed, discussing the various types and the nature of immunity. Chapter IV is devoted to toxins and antitoxins. Chapter V to agglutinins and precipitins. In this chapter the Moss and other classifications of isohemagglutinins are outlined.

Chapter VI deals with cytolysins, which lead naturally to a discussion of cellular resistance and this, in turn, to the fundamental theory of complement fixation and the application of complement fixation in the serum diagnosis of syphilis, tuberculosis, gonococcal infection and less common tests such as the complement fixation for glanders, smallpox and echinococcus cyst. Under the general heading of hypersusceptibility the topic of anaphylaxis is discussed, considering especially sensitization, various clinical phenomena of the reaction, passive anaphylaxis and the relation of anaphylaxis to immunity. This is followed by the study of serum disease and natural hypersusceptibility, the latter more especially in connection with the technique of cutaneous tests for the identification of the presence of toxins in hay fever.

There are three valuable appendices; first, one on therapeutic employment of blood serum; secondly, prophylactic vaccination; and the third, on vaccine therapy. This book is in every way practical, and, considering the extensiveness of the subject of immunology, encompasses in the smallest space what clear exposition of fundamental principles will permit.

THE CROONIAN LECTURES ON THE PSYCHOLOGY OF THE SPECIAL SENSES AND THEIR FUNCTIONAL DISORDERS. Delivered before the Royal College of Physicians in June, 1920. By ARTHUR F. HURST, M.A., M.D., Oxon, F.R.C.P., Physician and Neurologist to Guy's Hospital. New York: Oxford University Press, American Branch, 1920.

THESE lectures published complete now in book form appeared soon after their delivery in shortened form in the *Lancet*. Beginning with a talk on the nature of hysteria, the reader is carried through cutaneous sensibility and cutaneous anesthesia, pathogenesis of hysterical cutaneous anesthesia, sensibility and reflexes of mucous membranes, cutaneous hyperesthesia, hearing, listening, and hysterical deafness, hysterical hyperacusis, then seeing, looking, and hysterical blindness. While the book covers little more than 120 pages, it adds a very decided quota to the sum total of the knowledge of the abnormal side, as well as of the normal, of the behavior of the special senses under certain given conditions. To students of the new psychology this particular aspect of this field is presented in a concise, clear, and thoroughly enjoyable manner. Of course the style is delightful and the illustrations all that could be desired.

LES EXTRAITS HYPOPHYSAIRES EN OBSTÉTRIQUE ET EN GYNÉCOLOGIE. Par le Dr. LÉON POULIOT. Prix 5 francs. Paris: L'Expansion Scientifique Française, 1921.

THIS little volume is one of a series termed "L'Actualité Obstétricale et Gynécologique." Of the 96 pages, about 20 are used for a bibliography. An introduction is followed by a long chapter on the obstetrical use of the extracts and short ones devoted respectively to the gynecological and surgical uses. In the obstetrical chapter, there are nine subsections, on the normal physiological action, action in inducing labor, oxytoxic properties, action of the extract in puerperal hemorrhage, action in surgical accouchement, accidents and contraindications, indications, technique of exhibition and use of synergists.

UEBER DAS SCHICKSAL DER KRIEGSBLINDEN UND IHRE VERSORGUNG, ETC. Von Dr. Med. KURT UHTOFF. Preis 9.50 Mark. Halle a. S.: Carl Marhold, 1921.

THIS brochure of over 100 pages belongs to the "Sammlung swangloser Abhandlungen aus dem Gebiete der Augenheilkunde" and is devoted principally to the blind of Silesia. Among the 15 chapters some are devoted to such subjects as blind men's dogs, marriage of the blind, choice of residence, sources of income, etc. The greater portion of the book is devoted to the preferred occupations of the blind, some of which are old, while others are comparatively recent. Among the latter may be mentioned telephone operation and the manufacture of cloth shoes, the same being an industry developed as a result of the war. In addition to the stock occupations of the blind are also discussed music and teaching, the latter being adapted to those already educated along these lines.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 17, 1921.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

THE program of the evening was arranged in cooperation with the Section on Otology.

Progressive Systemic Deafness as an Endocrine Syndrome.—Dr. JAMES G. CALLISON made this presentation, in which he first stated that, according to present teaching, patients with progressive deafness and tinnitus were placed in one of three categories namely, chronic catarrhal otitis media, otosclerosis, and nerve deafness. In each case there seemed little justification for creating separate entities for the conditions. Attributing them to a systemic disturbance based on a pluriglandular dyscrasia correlated the symptoms in a rational way, making their etiology definite and concrete, and placed their treatment on a physiological basis. The systemic evidence of this pluriglandular dysfunction accompanying progressive deafness, whether in a casual relation or not, was present in all the tissues and organs of the body. This included the blood and vascular system, the skin and its appendages, the digestive tract, the nervous system, and the genitourinary system. In many instances the changes in other parts of the body were more marked than in the ears themselves. The general aspect of these patients was that of age. This might be in actual years or they might be aged beyond their years. The hair was gray beyond their years, was dry, lusterless, and might be falling out. The skin was wrinkled, dry, and chapped easily. The eyes were dull and expressionless. The glandular secretions generally, so far as could be observed, were disturbed and less abundant. These patients were overdressed for warmth, even in summer time, and stood winter weather badly. Mentally they were apathetic and lacked interest. They were rarely in a hurry, fatigued easily, and slept badly, and yet might be drowsy during the day, especially after a heavy meal. Constipation was nearly always complained of, and in women there were mental disturbances. Generally their energy was at a low ebb. The cardiovascular system lacked tone. The blood pressure varied, but was inclined to be low in uncomplicated cases. The pulse pressure varied and was not constant. Occasionally the blood pressure was high at the menopause period. Arteriosclerosis did not seem to be present in many of the patients treated for progressive systemic deafness. In these deaf patients the teeth were nearly always decayed. There was often an increase of both calcium and phosphorus in the urine, which undoubtedly indicated changes in the temporal bone and possibly in other bones of the body. There was likewise no doubt that the ligaments underwent certain changes resulting in a lack of tone in the ear as well as throughout the body. These patients came to the otologists complaining of progressive deafness and head noises, one or both. There was no constant quantitative relation between these two symptoms. Summing up the findings in these cases, it might be said that the local speculum examination helped but little in making a diagnosis. The functional examination of the ear gave more light on the condition, and yet the picture was inconstant. The symptoms, the changes in bone and air conduction and nerve reception were too well known to require discussion. There was one point, however, not sufficiently stressed, and that was the qualitative failure of sounds to register in the higher cerebral centers. The sound registering apparatus was interfered with rather than the noise perception apparatus. The three periods of life at which progressive deafness most commonly had its onset were puberty, adolescence, and the menopause, and to this might be added the oncoming of actual old age, and in some instances pregnancy. In discussing the glandular involvement in connection with progressive systemic deafness, Dr. Callison stated that it was not possible in the present state of our knowledge to say with any certainty which of the glands of internal secretion were the ones involved in progessive systemic deafness; it was possible, however, to mention some of the glands that were responsible for this syndrome. These included (1) that group of glands involved in the control of calcium and phosphorus metabolism; (2) those glands concerned with the control of oxidations in the body. The most important of these was the thyroid gland and next in importance were the sex glands and the suprarenals. After discussing the rôle of these glands the question of heredity was considered. It had been quite well established that what was commonly called heredity played a part in the etiology of progressive deafness, and it seemed entirely possible for a tendency to a weak or subnormal glandular system to be transmitted by true inheritance and this undoubtedly did occur. However, the great mass of socalled inheritance must be credited to intrauterine acquirement, due to the fact that the mother did not have sufficient of the gland substance to supply her own needs and those of the fetus. On the basis of thyroid deficiency and sex gland loss the pathology and symptoms of local ear conditions could be explained. The pathology of minor thyroid dyscrasia was essentially that of the socalled cellular infiltration. Suboxidation more accurately described the condition present. The pathology of gonadal deficiency was that of a mild fatty degeneration, with bone changes that were undoubted but not well understood. Combining these results into a coherent picture one found infiltration and cell crowding and mild myxedematous and fatty degeneration. As a result there was poor circulation with further depression of metabolism. With this there were changes in the phosphorus and calcium metabolism, due to the faulty action of the glands. In addition there was increased cellularity in the vascular and Haversian spaces of the bone. Later in the stage of atrophy there might be absorption and contraction of the cellular elements and a condition of osteoporosis supervened. These changes were applicable to the structures of the ear, including the nerve tissues. In the treatment of patients with progressive systemic deafness, inflation was to be wholly condemned. The drum membrane, the ligaments of the ossicles, and the middle ear muscles were already below normal as to their tone, and inflation reduced the tone they had left. In the treatment of progressive systemic deafness, foci of infection in the teeth, tonsils, or elsewhere, must be removed, inasmuch as these infections threw an increased load of detoxication on the glands of internal secretion and rendered their action less efficient. To obtain the best results endocrine treatment must be instituted at the earliest possible moment, since a time would come when degenerative changes had reached such a stage that regeneration and restoration of function were not possible. In the application of endocrine therapy to the relief of deafness there was no routine treatment. Such treatment should only be undertaken after a study of the principles of treatment and physiology from the standpoint of the glands of internal secretion, and there must be individualization in each patient treated. With these reservations, the writer stated that he had treated many patients with Harrower's adrenospermin compound, this being applied to the socalled thyroid type of patients. If the patient was suffering from both pituitary and thyroid symptoms, then he began with Burrows and Wellcome's mixed gland No. I or II, as the case might be. With functional high blood pressure, as in postmenopausal conditions, the situation became more complicated. Here there was an overactivity of the adrenals with a depression of the sex gland function. The result was that the adrenals lacked control. For the relief of high blood pressure a number of endocrines had proved useful, and among these sex gland substance was most important in the cases under discussion. If the blood pressure was normal or high, the treatment would consist of a combination of thyroid and sex gland, the proportion of sex gland being increased as the blood pressure increased. The dosage must be kept small, as the administration would of necessity extend over a long time. The initial dose of thyroid should not be more than ⅛ of a grain, usually less. Occasionally in those patients in whom the preservation of hearing necessitated the continued administration of endocrine substance, there should be intermissions extending over one or two months, or even longer periods if the gland deficiency would permit it. In the writer's series of

20 cases of progressive systemic deafness in private practice treated by endocrine therapy, 16 showed an increase in the distance at which they heard the whispered voice, and four had not increased the whisper distance. For the 16 patients who showed increased hearing distance, the average for the affected ears was 6 feet. If the ear showing the greater improvement, namely, a useful increase in hearing, was considered, then the average improvement for the 16 patients was more than 8 feet. The failure of registration of sounds had shown a marked improvement in all the patients treated, and had amounted to a very substantial increase in the ability to hear the whispered voice. A large number of patients had been treated in the clinic at the Post-Graduate Hospital. In these the deafness was usually more advanced and of longer duration than in the private patients, and his impression was that the improvement was about half as great as in the series of private patients. The more advanced the condition and the longer it had been present, the less favorable and the less complete the response to endocrine treatment.

Endocrinology in Otology.—Dr. CHARLES E. DEM. SAJOUS of Philadelphia presented this paper, in which he gave a comprehensive review of the subject of endocrinology. He said, in part, that in order to interpret with any degree of lucidity the clinical relationship between the few common aural diseases and the endocrines it was found necessary to ascribe to these glands the functions which he had attributed to them in 1903 and 1907. The subject had been very much confused. For example, we had been taught for many years that the function of the secretion of the adrenals was to sustain the function of the cardiovascular system, and that as a therapeutic measure it would raise the blood pressure. But other physiologists found that far from raising the blood pressure adrenalin, particularly in small doses, lowered it. We were told that adrenalin possessed antitoxin properties, but physiological experiments were advanced to show that it did not. If we treated the question with harmony as our watchword, quite another state of affairs asserted itself. We then found that far from being erroneous, all the functions described, mutually antagonistic though they seemed, were entitled to a legitimate place. This, however, was subject to one condition, namely, that they be considered as but expressions or manifestations of a *fundamental* function submitted by the writer a long time ago. In 1903 he had attributed to the adrenals the all-important function of endowing hemoglobin with the power to take up oxygen in the pulmonary air cells and of converting it into oxyhemoglobin. The adrenals thus became the governing organs, so far as oxygenation was concerned of metabolism throughout the entire body. Dr. Sajous reviewed the data which showed that this function was the fundamental one of these organs. If this function was applied to the different rôles attributed to the adrenals by the various physiologists, its harmonizing influence would reveal itself. Thus large doses of adrenalin, by increasing oxygenation and metabolism of the cardiovascular muscular elements, caused a general rise in blood pressure, and might thus maintain vascular tone; smaller doses, however, through the same process, only caused constriction of the ends of the vessels which were supplied with nonstriated fibers, the terminal arterioles and the heart. This also caused a rise, though passive, of the blood pressure since the constricted arterioles dammed up, as it were, the blood behind them and increased the tension in the larger vessels. The observation of Moore and Purington that minute doses caused dilatation of the arteries was also sustained, for such doses affected primarily the vasa vasorum, thus reducing the arterial blood supplied to the coat of the vessels and causing their relaxation. The antitoxic theory of Abelous and Langlois and Cannon's emergency theory could likewise be harmonized by taking the writer's viewpoint of adrenal function. As to the practical bearing of this function in otology, patients were frequently encountered who responded poorly to every remedial measure attempted, pharmacological or surgical. Such cases in many instances suffered from hypoadrenia. Such patients presented the symptoms of deficient oxygenation incident upon adrenal deficiency which not only rendered them vulnerable to infections, but also made of them poor operative risks. Moreover, such patients constituted a large proportion of the chronic cases in which purulent exudates prevailed. Turning to the thyroid, the discord was not so great, physiologists and clinicians being in agreement concerning the influence of this gland upon metabolism. This effect upon metabolism Dr. Sajous explained by his theory that the phosphorus of all nucleins, beginning with the phosphorized fats, was the element mobilized by the active principle of the thyroid hormone, iodine. The normal vital activity of the cell was dependent upon the perfect equipoise of the thyroid and adrenalin hormone present. Cases deficient in thyroid in whom the nuclear phosphorus was sensitized inadequately and oxygenation correspondingly reduced were particularly liable to nasopharyngeal infections with aural complications through the eustachian tubes. This was due to the lowered germicidal activity of the vault where the defensive barriers were of the utmost importance owing to the constant inhalation of bacteria-laden air. The essayist regretted the neglect in this country of the rôle of the thyroparathyroid apparatus in the immune chemistry of the body, now fully recognized on the continent of Europe. It was not only a function that might be utilized to treat successfully many obscure disorders, but one which, when abnormally active, as in hyperthyroidism and dementia præcox, might cause great suffering, insanity and death. Many bacterial studies had shown that the thyroid hormone seemed to sensitize every pathogenic organism, precisely as it did tissue cells to the bacterial action of antibodies, and an equally large number of investigators found that hyperplasia of the gland was present in febrile diseases though absent in nonfebrile. Farrant, after studying the subject in a large number of diseases, including tuberculosis and syphilis, stated, for instance, that "repeated injections of diphtheria toxin lead not only to thyroid hyperplasia, but also to the formation of antitoxin," thus confirming the writer's earlier contention. Given, then, a case in which hypothyroidism existed along with some deep-seated suppurative aural disorder which could not be eradicated by local treatment, the desired result would fail to be attained unless thyroid or iodine in some form was administered internally. Irrespective of an increase of antibodies evoked by other means, the pathogenic organisms would remain masters of the situation unless they were prepared for their proteolytic action by the sensitization which an adequate amount of thyroid hormone insured. Thyroid gland possessed another property, particularly if given with suprarenal gland or hypophysis sicca, that of increasing the coagulability of the blood. Even with hemophilia present he had seen the coagulation time of the blood reduced to three minutes. Another function which the thyroid body carried on was that of promoting calcium metabolism. In this connection reference was made to the pancreatic internal secretion as a factor in the defensive process; it supplied the enzymes which took part in protein metabolism, and in our defensive functions. The activity of these enzymes was increased by heat. The rise in temperature, produced by excess of thyroid and adrenal, increased the digestive activity of trypsin which, in both the phagocytes and the blood, digested the harmful agent. This process possessed a kinship to fever which, he believed, would be shown to be a defensive reaction carried on by the ductless glands. In discussing the pituitary gland, Dr. Sajous reiterated the belief that it possessed no active secretory principle. This, however, did not militate against the pharmacological value of posterior pituitary preparations. In fact, it explained their usefulness; they contained the constituents of both the medulla and the cortex of the adrenals and were therefore far more efficient than adrenalin to counteract circulatory failure, and also more lasting in their effect. Recalling the defensive rôle of trypsin, deafness resulting from the acute suppurative otitis media following acute infections of childhood was due not to the direct action of the pathogenic bacteria themselves, but to the local autolysis or digestion of the drum and other structures by the trypsic ferment which should serve to destroy the local bacteria and their toxins. Indeed, bacteria were not necessary to cause such lesions. In aural disorders developing at the height of a nasopharyngeal disorder, when the fever

was high, severity of the lesions might be mitigated and subsequent deafness might be prevented by hypodermoclysis, which served to prevent local lesions in endocarditis, pleuritis, etc. Organic preparations should not be employed during the acute febrile period of these diseases since they simply increased endocrine agents causing the proteolytic process and thus activated the autolysis to which the lesions were due. The case was different when the febrile period had passed. Thyroid should be avoided as long as the heart was weak. When the blood pressure was low the hypophysis sicca in 1/10 grain doses was better than even adrenalin. It was often an advantage to combine these agents. A comprehensive research upon the action of mercurials had shown that mercury was perhaps the most powerful stimulant of the ductless glands at our disposal. Calomel was also a potent adjuvant when antioxin failed to act. When one remembered the bactericidal activity of the defensive enzymes, the relief afforded by the application of heat to an affected ear became clear; it enhanced the local fever and hastened the destruction of the local pathogenic bacteria and their toxins. So far as the ductless glands were concerned, nerve deafness probably occurred when the acoustic apparatus was either rendered ischemic or deprived of the endocrine substances which sustained their oxygenation and metabolism. Here the aim was to increase the blood supply, which might be done by giving nitrites, sweet spirit of niter to begin with, or arsenic. In the forms directly traceable to adrenal insufficiency, the adrenal principle was the logical agent to use. Hypophysis sicca, embodying the action of both suprarenal cortex and medulla, 1/10 grain, with strychnine 1/50 grain, given in capsule three times a day after meals, might prove useful if destructive lesions, or atrophy of the cochlear nerve was not complete. It was suggested that possibly the cause of sclerosis might be sought in the endocrine glands, since this condition usually appeared at an age when senile hypoadrenia occurred; endocrine therapy might find an application in this condition.

Dr. Charles Edward Panoff said that Dr. Callison and Dr. Sajous had so ably cited their cases that anyone hearing them would come to the conclusion that endocrinology was a very important subject, and that it had a bearing on all branches of medicine, including so precise and limited a specialty as otology. They had proven that a knowledge of endocrinology meant a better diagnosis, and what was more important to the patient, a better therapy in otological cases. In studying a case along endocrinological lines we must remember the following facts: (1) That inherited tendencies had a marked influence on the endocrines of the individual and therefore on his development; (2) that they took part in the process of metabolism; (3) that they controlled all vital functions, and (4) that they were intimately correlated and cooperated in their functions. There seemed to be a better cooperation among the endocrine glands than among the endocrinologists. They were so correlated that when one got out of order the others got out of order, that when one failed to perform its proper function the others would endeavor to take up the work of the slacker. This taking up of additional work might be the cause of their own derangement. It was this cooperation which made it impossible to say that this one, or that one, was of a definite gland type either thyroidal, pituitary, or adrenal. While it was true that certain signs and symptoms might point to one of the main glands as the chief offender, still the speaker felt sure that when one who had that fine detective ability saw the case, so necessary for the making of a proper endocrine diagnosis, he would discover clues pointing to the other glands as accessory agents in the causation of the primary trouble. Personally he did not believe in single glandular derangements. He was in favor of the pluriglandular derangement theory, and of pluriglandular (extract) treatment for these derangements. The three main glandular systems, the thyroidal, the pituitary, and the adrenal, had a marked similarity of function: (*a*) They were stimulated by and in turn stimulated the nervous system; (*b*) they all lowered carbohydrate tolerance; (*c*) they all acted and reacted with the reproductive organs and (*d*) they all took part in the process of immunity. We all knew that there were certain classical diseases that were caused or were supposed to be caused by a hypo- or hyper-activity of these main glands. Thus we had cretinism, myxedema, Graves' disease, infantilism, Froelich's syndrome, acromegaly, Addison's disease, and in all cases the main symptom was hypertension. In all these diseases we had ear symptoms. The readers of the papers of this evening had gone fully into that part of the subject, so there was no need of repeating it. But they did forget to mention this fact that while certain ear conditions were caused by glandular derangements, certain ear conditions were also able to cause glandular derangements. Dr. Callison had read a paper along these lines before the section, but the majority of the members did not coincide with his views. However, it did raise enough interest in the subject of endocrinology to make the program of this evening a possibility.

Dr. Raphael Lewy expressed the opinion that the discussion of a paper depended on one's individual conception of the subject. He considered it a privilege to have listened to the paper of Dr. Sajous, which was the result of extensive experimental work and a vast clinical observation. Such a clinical and scientific paper could not be discussed within a few minutes. His conception of the study of endocrinology, and what knowledge he had acquired in relationship to it, he attributed to the teachings which he had received from the late Dr. Joseph Fraenkel who, in his opinion, was not only a scientific physician and clinical observer, but also a master in endocrinology; and if he compared some of these teachings that he had retained from this master he must admit that some of these statements made by Dr. Sajous and his findings were not compatible with the views of his late teacher. Otosclerosis, if he considered the morphology of the tissues and their physiological function, indicated to him that there existed a disease which was destructive to the intervening tissues and to the adjacent bony articular surfaces, constituting a hyperostosis which resulted in an ankylosis of the stapediovestibular articulation. Whatever the conception of the disease might be as to the primary focus and tissue involvement, whether such disease primarily involved the membranous labyrinth or whether the affection involved the bony labyrinth and destroyed the cartilaginous element of the bone, replacing it by bone tissue and therefore causing an ankylosis, he might state that there seemed to be a diversity of the opinion among various otopathologists as to the primary lesion of the disease. If one attributed this disease to a defective endocrine balance, the question arose: First, was there a similar condition in other parts of the anatomy? In answer, he might state that to him the disease resembled, whether it began in the membranous portion or in the bony portion, an intraarticular lesion of any other joint which in consequence of the destruction of the intervening tissues between two articulating bones resulted in an ankylosis. Considering that this disease would come under the category, if we considered the teaching of the older masters, of imperfect metabolism and therefore nonsufficient elimination of waste material causing retention of such waste material in the economy and secondary changes in the joints; and knowing that such deficit was governed by the thyroid gland, he would consider that the disease was subthyroidal and would most likely in very many cases react to thyroid treatment if given early in the disease. Secondly, if we considered our more recent conceptions based on laboratory findings, that the disease might be secondary to an infection from a primary focus or an infection primarily at the site of disease, we could also advance the hypothesis that the defective thyroid lowered the local resistance toward infection and caused a nidus for the development of bacteria. This would also classify the disease as a subthyroid condition. As endocrine pathology meant the dissociated balance in the function of several glands, no condition could be treated monoglandularly, and therefore in the administration of endocrine therapeutics the individual must be carefully studied as well as the local disease.

Dr. Samuel Wyllis Bandler said he had accepted the invitation to discuss the paper dealing with endocrinology in relation to otology, first, because it gave him the opportunity to express his appreciation to Dr. Sajous for his masterly review of the subject, and, sec-

ondly, because it gave him the opportunity to call attention to the need of observing the by-effects when endocrines were administered. One should not only focus his attention upon the object he sought to obtain when he gave the prescription, but should observe all effects that might be attributable to the endocrines administered. For example, he had had a patient, seen about four months ago, who complained of a peculiar hissing sound in her right ear. She had been referred to him by an otologist. She had a decided and progressive amenorrhea. While treatment relieved the amenorrhea she received no relief from the condition of the ear. About three weeks ago she received 5 minims of adrenal hypodermically. She stated that the second day after taking this the peculiar noise ceased for a day. He again gave her 5 minims of adrenalin and again on the third day the hissing noise was absent. He had repeated this dose of adrenalin several times, and each time with the same result. The last time the adrenalin was given the noise was absent for two days. This was one of the by-effects of endocrine therapy that might bear important information for those interested in other specialties. In that way we might get confirmation of what he believed was one of the most important questions in medicine, namely, that all the disturbance of sensation, such as hyperesthesia, parasthesia and all perversions of the senses, had a basis in the end apparatus of the nerves or in the centers that received impressions, and that we would no longer use the term psychogenetic for all such abnormalities and for abnormalities of the mind. It was also our duty to impart to the laity the fact that there was a physical basis for hallucinations, phobias, fears, etc., and that they were not entirely psychogenetic. In many cases physical changes were responsible for perversions of sense. These physical changes were dependent upon endocrine disturbance and could be treated more successfully by proper endocrine therapy than by relying upon psychoanalysis or its Freudian application; for dementia præcox, for instance, had a well-defined and almost characteristic pathology and the microscope showed the brain cortex, basal ganglia, etc., involved by biochemical dystrophies dependent upon endocrine abnormalities.

Dr. JULIUS J. HERTZ stated that Dr. Callison had said that all of his cases belonged to the group of hpyothyroids. He said there was a series of cases which did not belong to that group, as Dr. Beck and Dr. Pollock of Chicago had shown. Their cases belonged to a hypoadrenal and hypopitiuary group. Therefore one could not conclude that the disease was due either to a hypothyroid or a hypoadrenal condition. He felt that deficiency in the endocrine system was frequently inherited and, as had been pointed out, these patients were subject to infections, and consequently focal infections and toxemia played a large part in the ear condition. Dr. Callison had spoken of infiltration in the drum membrane and ligament; he would like to know whether he had done any autopsy work to confirm that. He did not know that so much experimental and clinical work could be condensed into one paper as Dr. Sajous had done. He thought the conception of some men regarding the treatment of these conditions was absolutely wrong. The idea of some men seemed to be to give as much of a glandular substance as they thought the patient was lacking. His conception was entirely different. He believed that unless the organ was completely destroyed one should give small doses not often repeated, as the drug was not given to replace the substance that was lacking but to stimulate the portion of the organ that was left and in that way to bring it up to normal function. Kendall advised giving minute doses of thyroid and showed that it took several days for the increased activity of the thyroid to manifest itself. The activity continued to increase up to the tenth day and then declined until the twenty-fourth day.

Dr. CHARLES F. STOKES said that, acting on the belief that the hypophysis was the master gland of the endocrine system and that it and sometimes other glands were structurally or functionally disordered by the toxins of infectious disease, focal infections, psychic stresses, and the like often leading to developmental abnormalities and other pathological manifestations, an attempt was made to electronize the pituitary and other glands to reestablish electronic balance in them, and thus bring about a rejuvenation of structure which would react upon the projecting apparatus of special sense organs and possibly the various channels and tissues of association, correlation, and integration. In his research work in recent years, Dr. Stokes stated that he had assumed that electronic equilibrium in the human cell structure was a natural and normal condition and that any upsetting of this equilibrium from any cause meant an unnatural and abnormal condition, indicating disease or disorder. In the use of the term "electronic equilibrium" he assumed, in line with the electron theory, that all forms of matter were exhibitions of electrical phenomena. Dr. Stokes then referred to the experiments made at Harvard University with the Coolidge bulb in regard to the measurement of electronic energy, and stated that the results of these investigations suggested the possibility of the *x*-ray furnishing a means to restore electrical equilibrium or health in cell structure. The account of these investigations was given in the Twelfth Kelvin Lecture by Sir William Bragg, before the Society of Engineers in London, January 13, 1921, and an editorial on this lecture was published in *The Electrician*, January 28, 1921. In applying these principles to the electronization of the pituitary-auditory region, a heavy lead foil screen was used, an aperture of 2¼ inches; chamois for aluminum radiation; 3 mm. aluminum filter; distance from the target 2 feet; 8 milliampères; time 15 to 20 seconds on each side. This dosage might be used from once to twice a week, depending upon the character of the response. With these precautions this practice was free from danger particularly as it was rarely necessary to prolong treatment further than two months. The usual remedial measures should supplement electronization. Impaired hearing and deafness from chronic otitis media, deaf mutism, epilepsy, and various disorders from endocrine imbalance, had yielded astonishingly good results. In the field of preventive medicine, particularly during convalescence from infectious and other diseases this procedure should be of decided benefit. At another time when cases had been sufficiently studied and tabulated this work would be reported upon more in detail.

Dr. HAROLD HAYS said that the different opinions of endocrinologists had been interpreted in such a way that they had not been able to come to any definite conclusions as to the use of endocrines for otological purposes. That the general bodily condition played an important rôle in the otological condition was recognized, but a word of warning should be sounded. We were going through certain phases, or he might say crazes, in medicine; for example, many cases of tinnitus were being sent to the psychoanalyst, and the patient was given advice which, if not harmful, did little good. Then again radium was used for the cure of tinnitus, and radium was used for all sorts of neoplasms and for some conditions in which there was no neoplasm at all. Coming to the endocrines, it was possible that the employment of the *x*-ray externally would stimulate the endocrines to do their work. On the other hand, in giving so much attention to these agents we were getting very far from otology. There were localized conditions which might come from the nasal passages, or from the Eustachian tube, and acute catarrhal conditions that could be improved by the otological methods used at the present time. If we used adrenalin for deafness we were going very far astray. Giving five minims of adrenalin every few days might have decidedly harmful effects. Adrenalin in certain conditions had temporary effects which had no relation to otology whatever. While he believed that endocrinology was worth while studying, patients should be treated in a common sense way and our energies should not be misdirected.

Dr. F. E. MULLER told his experience with a number of patients suffering from such conditions as tinnitus, otosclerosis, deaf-mutism, etc., who had been greatly improved by Dr. Stoke's method of treatment. In the application of endocrine therapy he stated that he was strongly in favor of the use of pluriglandular extracts. One could secure harmonious action only by a proper combination of the various glandular extracts, and of all the gland extracts he believed that of the hypophysis was the great harmonizer and stabilizer.

Dr. CALLISON, in closing the discussion, said there were only one or two points he wished to answer. He had been accused of describing the thyroid type; what he had done was to describe his patients as he saw them clinically. If he had described the thyroid type it was because the thyroid type gave deafness. If one gland got out of order three or four others did also and one then got a combination of symptoms. Dr. Hertz asked whether any autopsies had been done. The man who did an autopsy could not judge of the infiltration as accurately as the otologist who looked into the ear. The otologist could tell the amount of infiltration in the drum but not actually behind it. He thought no otologist or endocrinologist would advocate the treatment of tinnitus with adrenalin; it might lessen the tinnitus for the time being but would not cure it. If one was going to improve the patient, better oxidation must be secured. He quite agreed with Dr. Sajous that if thyroid and adrenalin did anything, they increased oxidation and any medication that improved oxidation would improve the hearing condition; and in so far as the oxidation was better the patient would be better.

Dr. SAJOUS said he was sure they would not long disagree, because scientific facts were scientific facts, and one could not go behind them. When additional facts were available harmony would prevail. What Dr. Bandler had said of the by-effects was certainly true, and he would suggest that all those using endocrines watch for them, as it was very important to secure more information in regard to such by-effects. Dr. Hertz had referred to the influence of toxemia and had attributed toxemia to thyroid and other glandular dysfunction; certainly the endocrines were not doing their duty where toxemia existed. He could show a really remarkable case in which the thyroid was as large as an orange; after removal of the tonsils the thyroid receded within two weeks. In speaking of toxemia it was always important to remember the role of the thyroid. Dr. Hays referred to the use of drugs to excess. He also wished to emphasize the danger of employing glandular extracts without knowing their action. There were times when their effects were really pernicious.

Stated Meeting, Held April 14, 1921.

THE SECOND VICE-PRESIDENT, DR. RUFUS COLE, IN THE CHAIR.

Precancerous Dermatoses.—Dr. WALTER J. HIGHMAN read this paper, in which he said that within the past twenty-five years Dubreuilh originated the term "precancerous dermatoses" for a group of skin conditions having, as he thought, a predisposition to malignancy, to which they played the part of forerunners. Since that time the term precancerous had received rather uncritical endorsement and had acquired wide currency. Upon reflection it seemed an unhappy choice, for it possessed a catch-penny quality readily adapted for the fetish worship that was often accorded brilliant expression. Thus language instead of remaining a vehicle of thought became a slogan. These considerations were mentioned because in employing the term precancerous he did so rather to identify the group of conditions constituting the theme of the paper than to indorse the term itself. Whether a lesion was precancerous could be determined only in retrospect and at a time when it had become cancer. Before such a time the expression was only a prophecy. Let the term be accepted on its face value! The implication remained that there was a series of skin lesions, a substantial minority of which appeared to lead to malignancy. How often this occurred in previously apparently normal skin was not recorded. Likely enough the skin itself became precancerous at a certain age, and if the first stage of an epithelioma looked like a seborrheal wart, it by no means followed that all seborrheal warts would become malignant, and more than that all pigmented nevi would become cancerous. Precancerous dermatoses, or cutaneous changes appearing to possess a more or less direct causal relation to malignancy, fell into five relatively well defined groups: (1) Congenital anomalies. (2) Infections. (3) Irritations, mechanical, actinic, chemical, or preexisting dermatoses. (4) Regressive changes. (5) Unclassified, such as horns (related to lupus vulgaris), Darier's disease, Bowen's disease, Paget's disease, xeroderma pigmentosum related to congenital anomalies and regressive changes. Lupus vulgaris was the condition most commonly leading to the formation of horns, and the latter often led to epithelioma. At best this was rare. After discussing in detail the above mentioned groups, Dr. Highman stated that at best only a very few of them regularly led to malignancy, except syphilitic changes in the tongue, chronic *x*-ray dermatitis, and xeroderma pigmentosum. Rare as the last condition was, its malignant termination was inevitable; second in importance was chronic *x*-ray dermatitis; third, lingual syphilis. In all the other diseases or conditions mentioned that led to epithelioma this outcome was most unusual. The only way to determine the validity of the term would be by comparison between epitheliomata which rose upon preexisting lesions and those which developed in previously normal skin. This had not been done. Nearly every one with an epitheliomata stated that it developed as a "pimple" or "scale" which persisted for months or years. The conclusion was invariably jumped at that this must have been a precancerous lesion. And yet it would be at least as reasonable,—nay, more so, to consider that this had been the incipient epithelioma itself.

Clinical and Histological Features of Cancer of the Skin and Oral Mucosa. (With Lantern Slide Demonstration.)—Dr. JOHN A. FORDYCE made this presentation, in which he first quoted statistics relative to the frequency, sex, type, factors involved in the etiology, etc., of cancer of the skin. He stated that Broders of the Mayor Clinic studied 537 cases of squamous cell epithelioma of the lip, which represented 26.85 per cent. of 2,000 cases of general epithelioma. In this series of cases the lower lip was involved in 95.69 per cent.; the upper in 3.55 per cent.; the left angle of the mouth in 0.56 per cent., and the right angle of the mouth in 0.18 per cent. Fricke in a study of 1338 cases found 91.1 per cent. in men and 8.9 per cent. in women. In 2.2 per cent. of the men the upper lip was affected, whereas 14.3 per cent. of the women had involvement in this region. Warren found 4 women among 73 cases, 3 of whom were smokers. Ebel reported 199 cases of cancer of the lower lip of whom 14 were women. Broders in his study found the proportion of males to females to be 49 to 1. Lane in a series of 122 cases found five women. Piquantin estimated that 17 per cent. of all cases of cancer of the tongue and mouth occurred in women. Thus it was evident that cancer of the mouth and lip were by no means confined to the male sex. Hazen estimated that 95 per cent. of cancers of the lip were prickle-celled; one-half of those of the upper lip were basal-celled. The factors that seemed to be involved in the etiology were syphilis, tobacco, and defective teeth. The frequency of syphilis was variously estimated. Meller found lues in only 7 of 207 cases of buccal cancer; Fournier found it in 155 of 184 cases; he held that 30 per cent. of leucoplakias were followed by cancer. Bergman found leucoplakia in 34.6 per cent. of 159 cases of cancer of the tongue. Other syphilitic lesions which led to cancer were localized wart-like epithelial hypertrophies, fissures, gummas with or without ulceration, and chronic glossitis with atrophy of papillæ. The epithelial overgrowth, submucous edema, lymphocytic infiltration, and eventual scarring with loss of elastic tissue were microscopical features explaining the remarkable relation between lues and cancer of the tongue. In Broders cases four-fifths were users of tobacco and one-half of all the women. Broders found his cases most frequently in farmers; Lane mostly farmers and outdoor laborers, and he accounted for this by the action of the actinic rays upon the skin. Warty, superficially diffuse and leucoplakic lesions were of relatively slow course. Ewing stated that tumors of the tonsil, cheek, and antrum were often slow to involve lymph nodes. Metastases were favored by a typical structure, rather deep than superficial origin, long duration and presence of inflammatory complications. In 87.01 per cent. of Broders' series lymph nodes were removed. Of the cases in which the lymph nodes were removed 23.38 per cent. showed metastases. The users of tobacco operated on did not give quite as good total results as

non-users. Of the patients with metastases 17.3 per cent. were living and 82.6 per cent. were dead. No patient with cervical nodes or more than one group of any lymph nodes was reported living in this series. In Broders' cases the duration of the lesion was from 0.08 to 28 years, the average being 2.58 years. Dr. Fordyce then gave a lantern-slide demonstration of the clinical and histological features of the various forms of cancer of the lip, tongue, and buccal mucosa. He stated that superficial keratoses, basal-celled, non-metastasizing forms of epithelioma and rodent ulcer might be treated successfully by *x*-ray and radium. The squamous-celled type of epithelioma was exceedingly malignant and practically always metastasized early; it was a very serious condition. Biopsy, unless the growth was removed at once, was apt to be followed by a local extension of the disease. The initial lesion of syphilis sometimes resembled epithelioma, and gumma had been known to appear years after at the site of the initial lesion of syphilis, indicating that the *Spirochæta* must have remained latent in this locality. He thought that leucoplakia and the keratoses might be called precancerous conditions. It should be remembered that all leucoplakia was not of syphilitic origin and that it was possible to have a combination of syphilis and leucoplakia. Occasionally tuberculosis of the tongue and lichen planus might be mistaken for cancer.

The Treatment of Skin Cancer by X-Ray, Radium and Electrocoagulation. With Lantern-Slide Demonstration.)—Dr. GEORGE E. PFAHLER of Philadelphia made this presentation, confining his remarks to cancer of the lip and mucous membrane of the mouth. He declared that there were probably more mistakes and careless handling of this group of cases than of any other, and the mishandling of this group meant bad end results. He asked Dr. Fordyce in his closing remarks to tell him how soon he would expect results from antisyphilitic treatment in a case in which there was some question as to whether the condition was syphilis or cancer of the tongue. He said he asked this question because the most hopeless cases of cancer of the tongue that came to him were those that had been treated as syphilis. He believed that precancerous conditions could all be removed and treated successfully. The rule he followed was that when any lesion became irritated it should at once be thoroughly destroyed. He further believed that the best method for destroying precancerous lesion was by electrocoagulation. Warts, moles and angiomata could all be removed by electrocoagulation, but if one did not wish to have a scar, if the cosmetic result was important radium would produce less disfiguring results. Those lesions in which one was not so particular about leaving a scar could be easily, quickly and thoroughly removed by electrocoagulation, and by this means one immediately effected a destruction of the blood vessels. Certain lesions treated by *x*-ray and radium reached a stage at which regression ceased and if one wished to cause further destruction a dose of *x*-ray or radium was required which was destructive to the surrounding tissues. When a lesion reached this stage it was advisable to resort to electrocoagulation. In many instances, especially in severe cases, it might be advisable to combine two, three, or even four, methods of treatment, using radium, the *x*-ray, electrocoagulation, and surgery. In the treatment of epithelioma of the eyelids he preferred to use radium as there was less destruction of tissue than with electrocoagulation. In the use of radium one should give at least two or three erythema doses at the very beginning of the treatment and should keep the patient saturated with radium until the lesion disappeared. In the treatment of lesions of the ear electrocoagulation was in his opinion preferable because it produced results quickly and did not destroy the hair in the vicinity of the ear as the *x*-ray and radium might do. In epithelioma of the mouth and lip he preferred to use electrocoagulation and to follow it by the *x*-ray, and then the patient got well and remained well. He had never yet failed to cure an epithelioma of the lip in which the case came to him primarily and he had treated over one hundred cases. This, he said, did not mean that he would not fail, possibly with the next case. The cases that offered difficulty were those that had been treated by caustics, partial surgery, etc. He used the full erythema dose of *x*-ray filtered through a 6 mm. aluminum screen at a focal distance of 8 inches, using 5 milliampères for 12 minutes. In cases in which excision was decided upon *x*-ray treatment should precede and follow the operation. In cases in which a metastatic nodule was found in a gland, he had removed the primary growth by electrocoagulation, and had treated the nodule by the introduction of radium, with very satisfactory results. He stated that he believed that in the future many cases would be treated by this procedure. In advanced epitheliomas of the nose electrocoagulation had given very excellent results and in epitheliomas following burns. Where there was rather extensive destruction of tissue resulting from electrocoagulation plastic operation was then resorted to in order to repair the defects.

Surgical Treatment of Skin Cancer.—Dr. BURTON J. LEE made this contribution, in which he said that he had been very much impressed by two or three things in connection with skin cancer. The first of these was the need of absolute accuracy in the diagnosis of the numerous socalled precancerous lesions which might lead to carcinoma. Unless accurate diagnosis was arrived at, treatment was likely to fail. Dr. Lee said he spoke from the point of view of the surgeon who was endeavoring to find the truth in regard to treatment of these lesions by surgery and also by radioactive substances. Surgery was to be criticized when it would not honestly investigate the results of radioactive treatment. He spoke first of the melanomata, of which they had seen a considerable number at the Memorial Hospital. Most of these patients came following operation; he had yet to see a case of melanoma successfully treated by surgery. He could also say that he had never witnessed successful treatment by radium. At the present time there seemed to him no daylight as regards the treatment of this disease, other than by recognizing the precancerous stage and practising a wide removal, without handling of the pigmented mole. Squamous-celled epithelioma of the lip was always first a local disease. Even though there was some invasion of the deeper tissues it was still a local process and remained so for some time before the lymph nodes became involved. Inasmuch as it was an embolic involvement of the node rather than extension by permeation, its treatment might be considered in two categories: first, the treatment of the initial lesion, and, secondly, the treatment of the metastatic lymph nodes. The original tumor was very successfully and preferably treated by radium. Less deformity followed and the removal of the mass was completely accomplished. So far as the lymph nodes were concerned, he felt that they still offered a surgical problem, whatever the procedure for the original tumor. He had not seen success, such as Dr. Pfahler had described, in the treatment of involved lymph nodes at the Memorial Hospital. At present he preferred to treat these nodes by excision followed by the insertion of radium needles. On the other hand, basal-celled epithelioma or rodent ulcer was a condition which metastasized slowly, and remained local for a long time. Here one had the choice of wide excision by surgery or treatment by radium, which latter method he had seen used very successfully. In this type of growth excision by surgery resulted often in a disfiguring scar and the result was no better than by radium. He believed, therefore, that at the present time rodent ulcer was best treated by radium rather than by excision. Dr. Lee also emphasized the point brought out by Dr. Pfahler that cases that had been treated by the *x*-ray and had reached a stage where regression no longer proceeded were the most difficult to treat. The point he particularly emphasized was the necessity for early recognition and proper treatment at the outset, which meant initial large doses of the radioactive substance. Paget's disease in old women or in the very early stage might be treated by radium, but he felt that operable carcinoma of the breast was best dealt with by surgery.

DR. DOUGLAS A. QUICK laid further emphasis on the necessity for accurate diagnosis in these lesions, and brought out the point that the appearance of the growth when the patient first presented himself might mean very little, since some of the more benign forms might present a worse appearance than the more

malignant ones. In dealing with rodent ulcer and basal-celled epithelioma of the skin he thought one was permitted considerable latitude. He felt, however, that radium gave a better final result in that the scar was less unsightly than that following surgery or the electrocoagulation method. In lesions that were amenable to treatment by radium he felt that the only place that surgery was indicated was for the purpose of giving a better exposure for the use of radium. Many of the smaller basal-celled epitheliomas might well be treated by the electrocoagulation method because of its simplicity. When it came to the squamous-celled form of epithelioma it was a serious problem which must not be considered in the same class with the basal-celled type by any means. Some excellent results had been shown in the treatment of squamous-celled epithelioma by the electrocoagulation method but he would not like to trust to effecting a cure by this method. Some were in favor of using heat, but it must be remembered that heat was a devitalizing process and opened the lymph channels. In treating lip lesions the size of the defect had to be taken into consideration and of course the defect was not so great with the use of heat, but altogether he should not feel inclined to push its use too far. He thought radium should be used in the lip cancers. Those that extended along the surface of the lip and looked very bad were not always the worst cancers. In some of these it was not always necessary to bury the radium needles while a few could only be handled by burying the needles. Radium in these cases was very much less disfiguring than the other methods. After all, the chief problem in dealing with cancer of the lip was the cervical lymph nodes. Here he thought they were pretty much all agreed that external radiation was not effective, and that the radium should be buried in the affected node. Likewise in the eyelid where one wished to be conservative so that the eyelids could be closed radium was very essential in the treatment. In the use of radium two points must be emphasized: (1) Radium must be accurately applied, and (2) sufficient dosage must be used. One frequently saw lesions in patients who said they had been treated by radium, but evidently it had been used in such small doses that it had accomplished very little. He hoped that Dr. Fordyce in closing would say something about leucoplakia, and he hoped someone would say something more about the treatment of melanomas. Personally, he felt inclined to leave the pigmented mole that was quite stationary, but if there was any indication of activity radium offered the best hope of relief for the longest period of time.

DR. S. POLLITZER said that the impression that one would gain from the pictures that had been shown this evening was that epithelioma of the skin was a very serious disease. As a matter of fact epithelioma of the skin in the vast majority of cases was relatively insignificant. Furthermore epitheliomas of the lip and mouth constituted a relatively small proportion of all epitheliomas. Another point was that these pictures all showed advanced conditions, and that brought up the point he wished to emphasize. The public had the impression that so long as a growth was not painful and was not particularly disfiguring, it was not serious and consequently such growths were disregarded until they reached an advanced stage. The dermatologist, as a rule, did not see cancer of the internal organs, yet within a comparatively brief period he had seen a half dozen cases of cancer of the breast in women who had not sought medical advice for the condition. In one instance the woman had a large infiltrating ulcerated cancer of the breast and she had not seen a medical man. Upon being asked why she had not consulted a physician, she said she was afraid it might be cancer. In the second place the physician must be educated, for he was often to blame because he either neglected the case that might be cancer, or failed to recognize the condition, or else treated it improperly. With reference to leucoplakia as a precursor of cancer, he was inclined to think that it did not act as a precursor of cancer as frequently as was supposed. Dermatologists saw hundreds of cases of leucoplakia where they saw one of cancer; he felt that if leucoplakia were a frequent precursor of cancer they would see more cases of cancer than they were seeing. Leucoplakia occurred oftener on the tongue than elsewhere, and on the tongue it was more likely to become malignant than elsewhere. Personally, he liked the term precancerous, though he admitted that from the etiological standpoint it was absurd and from the prognostic point of view it might be wrong; but it had the advantage that these conditions frequently became cancerous and therefore it put the physician and the patient on their guard. The worst of all precancerous lesions was the pigmented mole. The management of the pigmented mole differed very much in practice by different physicians. Many left it alone and others were puzzled as to what to do. A melanoma that showed activity usually meant a death certificate. It was his rule to advise the removal of a pigmented mole before it showed any signs of disturbance if it was located in any region where it was exposed to irritation, and especially if it was on the foot, since it was well known that pigmented moles on the foot frequently resulted in general melanosis. He thought melanomata should be removed by the cautery rather than by the knife, and where the knife was used it was important that the lesion should not be massaged, for frequently massage of the lesion resulted in dissemination of the disease. In the management of these lesions, in operating one should not only follow the rule of wide excision but one should be careful not to massage the growth during the course of the operation. He thought the one important lesson that should be carried away from the meeting was the importance of the early recognition of these conditions and the fact that waiting might be fatal.

DR. WILLIAM B. TRIMBLE spoke of the treatment of these lesions in a general way. He thought the flat types of epithelioma about the face should be looked upon individually and that the selection of the method of treatment was a matter of judgment. Of course there were some cases that absolutely demanded radium, or *x*-ray, or electrocoagulation, while in others surgery might be preferable. At Bellevue they had treated some of these cases with the *x*-ray and he could show in a small way some rather spectacular results as a result of treatment by radium, nevertheless his leaning was toward surgery. He thought that if the lesion was accessible to the knife that the knife was preferable. Surgery could be applied by excision, curettage, or the cautery. There was no objection to excision, but if the growth were not large he rather preferred curettage or the cautery. The surgeon usually claimed that excision was better, but he thought that perhaps a growth could be removed with less manipulation with the cautery and this might also kill a few malignant cells that had wandered into the surrounding tissue. The main object was the destruction of the cancer tissue and any method that would do this was a proper method to use, taking into consideration distortion of the parts and the cosmetic effect.

DR. ISAAC LEVIN pointed out that cancer of the oral cavity demanded similar treatment to cancer in the other cavities as the rectum, vagina, esophagus, and that meant that the dermatologist had to send his patient to the druggist, the surgeon, or the radium worker. He did not wish to belittle the work of the surgeon, but he wished that more physicians would get into closer contact with the radium workers and see what was being accomplished. Speaking of the lymph nodes, Dr. Levin said the idea was general that they must be removed surgically, but in doing a block dissection there was always ample opportunity for scattering the cancer cells and the result was a local recurrence, hence he believed that the introduction of radium emanations or capillary spicules into the lymph glands was superior to straight removal because one could thus destroy the cells *in situ*. As there might be a few adult cells, as Dr. Pfahler had termed them—cells which were not destroyed by radiation—he thought the proper method of procedure was first to introduce radium, then to remove the gland and to follow the removal by radiation. He believed this was the correct method of cancer therapy in any location. He had used the same method in the treatment of cancer of the breast, cancer of the cervix, and other cancers. This procedure might obviate the need for electrocoagulation. He believed in radium first and then if necessary everything else afterward.

Dr. CHARLES M. WILLIAMS said the word precancerous might or might not be etymologically correct, but that was not the point. One must consider the facts. How many, he asked, had seen epithelioma arise from normal skin? Cancer usually developed on diseased skin. Some word was needed to describe that group of conditions of the skin in which epithelioma developed so we had better use the term precancerous. Impaired nutrition leading to atrophic conditions of the skin and scar tissue, characterized precancerous conditions. In lupus vulgaris, senile keratosis, *x*-ray dermatoses, etc., atrophy and scar tissue were the outstanding features, so the thing to do was to treat the patient so as to prevent these precancerous conditions. One should treat syphilis early so that scar tissue did not form on the tongue and cheeks. One should treat lupus vulgaris and senile keratoses properly because these were among the commonest forerunners of cancer of the skin. One should warn those who were continuously exposed to the actinic rays of the sun and instruct them to protect themselves against undue exposure. The first sign of warty degeneration should receive attention in the way of protection against irritation and the use of a bland ointment. An ointment of salicylates and sulphur was very efficacious in keratoma. He would not have it understood that he was treating epithelioma with the salicylates and sulphur, but before cancer had developed such treatment was effective. Dr. Williams also spoke of the danger of biopsy, and emphasized that the main point in the treatment of cancer was to treat it early and treat it vigorously, but not to fuss with it. Accurate clinical observation was of importance rather than placing entire reliance on the laboratory. It was well to remember that cancer might develop on a gumma and one might find a four plus Wassermann, but that lesion could not be controlled by antisyphilitic treatment. Dr. Pfahler had recommended two or three skin units at the start. He agreed with him in that particular; if one was going to treat epithelioma he should hit it hard at the start and not take half-way measures.

Dr. HIGHMAN said he had not intended to enter into an etymological debate but he felt that there was no reason for the use of such an absurd term as precancerous. He believed that all the cancers that developed on a socalled precancerous base would not amount to 1 per cent. of skin cancers. One of the speakers advocated treating cancer before it developed. How was one going to do that? There was a variety of socalled precancerous conditions how was one to treat them all? He felt that if a lesion was causing no trouble it should be let alone. As for the treatment of precancerous conditions with ointment, he did not believe that ointment ever prevented a cancer from developing, neither did he believe that cancer developed only on diseased skin. He said he wondered whether any investigator had collected statistics to show the number of cancers that had developed on skin that was previously normal. Of course the patient always said it started with a pimple, but the pimple in those cases was the first stage of malignancy, and to say that the cancer started as a pimple did not mean anything.

Dr. FORDYCE, in reply to Dr. Williams' question, said that leucoplakia in the majority of cases did not result in cancer. The difficulty was that these patients with epithelioma did not consult the dermatologist until they were too far advanced and until nothing could be done. He thought the general practitioner needed instruction in the recognition of lesions of the mouth. With regard to the treatment of syphilis, he would treat it until the Wassermann became negative. Under treatment the leucoplakia of syphilis improved or there might result a permanent condition resembling a keratosis. The treatment of a syphilitic lesion until the Wassermann became negative required a very indefinite period; it might be one year or several years.

Dr. PFAHLER said he had asked this question because it often happened that the general practitioner went on treating a lesion on the tongue as though it were syphilis for months and months when the Wassermann test was positive, without taking into consideration the possibility that the lesion might be malignant.

Dr. BURTON J. LEE, in closing, said that all workers in the cancer field should observe great caution in stating that cases are or are not cured. A better term was "satisfactory results to date." Those who were working in this field recognized the fact that recurrences might take place up to five, ten, or more years.

Dr. FORDYCE said it was not necessary to rely upon the Wassermann test. He thought a good clinician could tell the difference between syphilis and cancer. If a patient had a gumma it might be mistaken for cancer, but a very short course of antisyphilitic treatment would soon clear up the question if the lesion was in the transitional stage.

Dr. PFAHLER expressed the opinion that if they were going to treat all warts and moles as though they were precancerous it would sometimes be a pretty big undertaking. He cited the instance of a woman 84 years of age under his care for cancer of the breast with metastatic nodules. She had perhaps two hundred keratoses. He had told her to leave them alone unless they disturbed her. If a woman forty or fifty years of age had those lesions he might advise her to have them removed. Dr. Pfahler said he would not leave a pigmented mole on his body a day longer than he had to; he would have it destroyed by electrocoagulation and thoroughly destroyed.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held April 26, 1921.

DR. HAROLD BAILEY IN THE CHAIR.

Fatal Case of Rupture of the Uterus.—Dr. JOHN H. TELFAIR reported this case which occurred in a woman 32 years of age, para V. She gave the history that after having been in labor from 6.00 A.M. to 2.00 P.M., August 15, 1919, she was delivered by podalic version and extraction. The physician who delivered her left her shortly after delivery. About an hour after delivery the husband of the patient notified the attending physician that there was something wrong and asked him to return. He said it was not necessary and did not respond. About two hours after delivery the husband went to the physician and told him he thought his wife was dying. The physician said he would come after dinner. At 7 P.M. the woman was seen by the attending physician who immediately called an ambulance and sent her to Fordham Hospital. When admitted to the hospital at 8.00 P.M. she was in profound shock. If this woman had been seen within an hour or so of delivery she might have been saved. Examination upon admission to the hospital showed a deep laceration of the left side of the cervix extending upward to the lower uterine segment. Immediate laparotomy showed the laceration extending into the anterior uterine wall. A rapid hysterectomy was done and infusion given, but the patient died one hour later.

Complete Blindness Occurring During Pregnancy.—Dr. TELFAIR reported this case also. He said that the patient, 36 years of age, a para V., gave a family history showing cancer and tuberculosis. She had had four living children and three spontaneous abortions. Soon after becoming pregnant she noticed blurring of vision in the left eye. Following this the right eye behaved in a similar way. By the time she was ten weeks gravid she was completely blind. General physical examination showed a marked pyorrhea alveolaris and signs in the chest suspicious of a tuberculosis process in the right lower lobe. Examination of the eyes showed complete optic atrophy. The urine output was normal and repeated examinations were negative. The blood Wassermann was negative and the blood pressure normal. The spinal fluid was under slightly increased pressure. The *x*-ray examination showed no evidence of pathological lesion in the skull, there being no evidence of intracranial pressure and the sella turcica being normal. The blood chemistry examination showed normal results. The neurological examination suggested the possibility of a tuberculosis lesion involving the optic chiasm. Because of the marked pyorrhea most of the teeth were removed and the others treated. This had absolutely no effect upon the vision of the patient. She was admitted to the Hospital on February 17, 1921, and was due April 30. She continued totally blind up to the present time.

Dr. CHARLES GRAEF said he had examined the eyes

of the papilla. There was the appearance of complete optic atrophy. Optic atrophy, as they might recall, was roughly divided into two classes: (1) simple and primary atrophy, which came without any inflammation, usually due to such conditions as locomotor ataxia, paresis, or multiple sclerosis, etc. (2) secondary optic atrophy which followed inflammation of the nerves due to many causes. The disturbances of the uterus in pregnancy, and the toxemia of pregnancy were often among these causes. These two types of optic atrophy were distinguished by certain appearances of the fundus. In primary optic atrophy there was a thinning of the optic nerve as it came through the lamina cribrosa giving a so-called pepper-box appearance to the optic nerve head, with shallow cupping. In the secondary form which followed inflammation, there was an exudate and a deposit of connective tissue formation on the nerve head. One could not say with absolute certainty of course, but the indications were strong that this was a secondary optic atrophy. The woman must have had the optic neuritis at the time she became pregnant or soon after. These cases usually occurred in the later stages of pregnancy. If it were a primary optic atrophy there would be no hope of recovery of vision. Since it was secondary there might be a few nerve fibers remaining alive, and, as was well known, after delivery there was a general stimulation of absorptive activity throughout the body; it was possible that this might have some effect upon the optic nerves and that the patient might thus recover a certain measure of sight. It was not very promising however.

Dr. BAILEY cited a case that illustrated what might occur from the functional standpoint. A woman who had a preeclamptic condition in her first pregnancy and also in a third pregnancy, had in her second pregnancy at the eight month, one hour after rising, complete blindness. She was taken to the hospital and after an hour began to see a little. By 4 P.M. the blindness had quite cleared up. Her eye grounds were examined and nothing found. On the fourth day she returned home and went to an uneventful labor.

Dr. GRAEF said he had had a similar experience. If one did not find anything in the fundus and sudden passing blindness occurred it was due to uremia or circulatory disturbances in the optical cortex in the occipital lobes of the brain, or else it was a case of hysteria. Hysteria of that type was very common. This patient had no uremia so the blindness might be put down to hysteria or fleeting circulatory effects.

Eetropion of Abdominal Viscera, with Specimen.—Dr. M. O. MAGID presented this specimen of a stillbirth because of the rare occurrence of this condition and the small number of cases reported in the literature, and also because of the diagnostic difficulties it presented in the first stage of labor. The mother was a para I, 27 years of age. Her last menstruation was May 18, 1920. On February 5, the pains became regular and severe. Examination revealed an os dilated to the extent of about three and a half fingers, and extruding from it was a mass about the size of an orange. Adjoining this was a smaller mass about the size of a peach; there was a sulcus between them. The two masses were somewhat firm and seemed to be joined together higher up. The patient bled considerably at the time although her pulse, 90 per minute, was of good quality. The patient did not seem to be suffering from loss of blood. In the course of an hour the two masses presented themselves at the vaginal opening and with them came a loop of what at first seemed to be the cord, but was soon recognized to be small intestine, the two masses being lobes of the liver. Soon after these structures were born the remainder of the fetus was expelled in the transverse position in extreme extension. Instead of the cord, there were a few strands of tissue connecting the body of the fetus to the mother. These were tied and cut. The placenta, which was large and bore evidence of extreme fatty degeneration, was expelled spontaneously forty-five minutes later. The patient made an uneventful recovery and left the hospital on the tenth day. The fetus presented a normal appearing head, chest, and upper extremities. It appeared to be that of an eight months gestation. Instead of the abdominal wall covering the liver and intestines, there was merely a thickened peritoneal tissue layer. This apparently ruptured in utero. There was an absence of the bladder and genitals; the lower right extremity had no hip joint articulation and the buttock was missing. Both extremities were rotated so that the feet pointed toward each other. From their embryological data, it was apparent that the visceral arches failed to unite in the middle line, resulting in complete ectropion of the abdominal viscera.

Treatment of Syphilis during Pregnancy.—Dr. ALFRED C. BECK presented this preliminary report, which he illustrated with lantern slides. He stated that when he had been asked to read a paper on this subject he did not have his statistics in shape, and the time at his command permitted him to follow up only 73 patients giving four plus Wassermann reactions, 32 of which he had studied sufficiently to include in this report. A brief résumé of each of these 32 cases was presented. The study brought up the question whether they were justified in treating a pregnant woman as a syphilitic because she gave a positive Wassermann reaction, if there were no other evidences of syphilis. The study showed that women seen late in pregnancy and giving a positive Wassermann reaction frequently gave birth to nonsyphilitic infants, where five or six injections of salvarsan had been given. It was not necessary to render a mother Wassermann negative in order that the child might be Wassermann negative. The fetus in utero seemed to respond more readily to antisyphilitic treatment than the mother. Even one injection of salvarsan into the mother was of value as the infant born under these conditions responded readily to the treatment. The prenatal recognition of syphilis was of great value as with the knowledge of the presence of the disease the child could be treated immediately after birth. There was no danger in giving salvarsan late in pregnancy; it seemed to have no ill effect upon the kidneys and did not bring on premature labor. In only two cases was it necessary to discontinue the treatment because of the severity of the reaction. Even in threatened miscarriage itself due to syphilis one did not need to discontinue the treatment. A Wassermann test made on a child at any time under one month of age was of little or no value.

Dr. JAMES B. GIVIN stated that he had followed up most of these children and had been struck with the absence of luetic stigmata in them as compared with another group of children of syphilitic mothers who came to the pediatric clinic and who showed four plus Wassermann reactions. An interesting feature in these babies was the ease with which they responded to antisyphilitic treatment. They were given inunctions of mercury and not salvarsan. It might be that later on these children would show retarded syphilis. If any of the late signs of syphilis appeared it would emphasize the importance of following up these cases and keeping them under treatment, and repeating the Wassermann test at stated intervals.

Dr. GEORGE W. KOSMAK said he was interested in Dr. Beck's paper, particularly in the statistics he presented, and more so in his conclusion. He was afraid Dr. Beck was going to say that he had 32 cases of undoubted syphilis but he noticed that he modified that assertion somewhat. It seemed that it was scarcely fair to assume a positive diagnosis of syphilis even if one found a four plus Wassermann reaction. At the Lying-In Hospital they found the usual proportion of positive Wassermanns and a large number of tests were made. The babies were tested not later than two to four days after delivery. Many positive Wassermann babies were strong and vigorous and showed no evidence of lues. Therefore it made one rather doubtful whether he ought to make a diagnosis of syphilis where there was a positive Wassermann but no other evidence of syphilis. In women it was very difficult to get a history of a primary lesion and the secondary symptoms were so obscure that it was difficult to get any definite information. Of course we must have something definite to go by if we were going to establish a standard method of treatment for syphilitic patients but it was a question whether we should depend upon the specificity of the Wassermann test since it had been found that many other conditions give a positive Wassermann reaction—conditions having no relation to syphilis.

Dr. FREDERICK W. RICE said that at Bellevue and the Manhattan Maternity Hospitals they had been taking the Wassermann reaction on every pregnant woman and they had been giving vigorous treatment. If they found a positive reaction in the prenatal clinic they turned the patient over to the genito-urinary department for salvarsan treatment every two weeks with mercury between. The babies they treated for one month and then turned them over to the children's clinic.

Dr BAILEY asked about the alleged dangers of giving salvarsan. One case arriving at the hospital three days after its use presented the symptoms of acute yellow atrophy, and this patient died. The medical examiner refused to perform an autopsy because he said deaths from this cause were frequent.

Dr. BECK, in closing the discussion, said that when Dr. Healy asked him to read a paper on this subject he was able to find only 73 cases that had given four-plus reactions and of these only 32 had been followed up sufficiently to include them in a report at this time. Many more cases would be included in the complete report. In the beginning of the study the question came up "Did all these women have syphilis that gave a positive Wassermann reaction?" Up to eighteen months ago he had refused to treat a woman when she had a four-plus reaction and no other evidence of syphilis. The majority of these women gave negative histories, as was usually the case. Hence they had to rely upon the Wassermann reaction, and on account of the severity of the treatment he had insisted in having the Wassermann checked up by a second test, either in his own or in some other laboratory. Twenty-nine of these 32 women were definitely syphilitic. He felt that we did not know all that we should know about the Wassermann reaction in women during pregnancy and in the newborn. In none of the deaths in this series was autopsy performed so he could not say that syphilis had caused the deaths. With regard to Dr. Bailey's remarks, he did not hesitate to give salvarsan and they were giving it to a large number of patients. They had had a great number of patients who had had one, two, or three injections that were not included in this series. Hirst had said that he was afraid to give salvarsan in the last two months of pregnancy; most of the cases in this series had received salvarsan during the last two months of pregnancy without bad results.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF MARYLAND.

December 14-17, 1920.

(*Continued from page* 572.)

PATHOLOGY.

1. Discuss immunity?
2. What are miliary aneurysms; where are they found, and to what condition are they contributing factors?
3. How is human tuberculosis of the lungs supposed to be contracted?
4. Describe a calcified blood vessel.
5. How is the number of bacteria in a solution estimated?
6. Describe an hypertrophied prostate gland; if it leads to obstruction to the flow of urine, what reaction occurs in the rest of the urinary system?
7. What is the significance of a focus of infection; for instance, an infected tonsil?
8. What was Louis Pasteur; when did he live; what were his principal contributions to human medicine?
9. What is typhoid vaccine; what has been accomplished by its use?
10. What local and general pathological conditions are expected in a severe untreated case of diphtheria.

PRACTICE OF MEDICINE.

1. Give the symptoms and treatment of epidemic cerebrospinal meningitis.
2. Give the symptoms and treatment of acute catarrhal bronchitis in a child one year of age.
3. Give differential diagnosis of hypertrophic cirrhosis and carcinoma of the liver.
4. Give differential diagnosis of pleurisy with effusion and primary lobar pneumonia.
5. Give diagnosis and treatment of typhoid fever.
6. Name the complications which may follow measles and the period of isolation.
7. Give the etiology and the treatment for erysipelas. What precautions should the physician take?
8. How would you treat a case of bronchial asthma?
9. What are the causes of vomiting in infants and very young children?
10. Give the symptoms of dementia praecox.

ANSWERS.

PATHOLOGY.

1. *Immunity* is the power of resistance of cells and tissues to the action of pathogenic microorganisms. Immunity may be either natural or acquired.

Natural immunity is that power of resistance, natural and inherited, and peculiar to certain groups of animals, but common to every individual of these groups.

Acquired immunity is this resistance acquired (1) by a previous attack of the disease, or (2) by the person being made artificially insusceptible. The chief conditions which give immunity are: (1) A previous attack of the disease; (2) inoculation with the specific microorganisms in small numbers or of diminished virulence, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

Active immunity is that form of acquired resistance to infection which is brought about by the activity of the cells of a person or animal as a result of having had the disease, or as a result of artificial inoculation with a modified or attenuated form of the causative microorganism.

Passive immunity is that form of acquired immunity which depends upon defensive factors not originating in the person or animal protected, but is passively acquired by the injection of serum from one that has acquired an active immunity to the disease in question. It is a sort of secondary immunity acquired by virtue of having received antibodies actively formed by another animal that has had to resist the infecting agent in order to produce them.

2. *Miliary aneurysms* are small multiple aneurysms which may be found in small arteries at the base of the brain; occasionally they are present in the pulmonary and mesenteric arteries. They are supposed to be due to some congenital weakness of the vessel wall, and are regarded as precursors of cerebral hemorrhage.

3. *Human tuberculosis of the lungs is supposed to be contracted* by the entrance of the tubercle bacilli through the respiratory tract by inhalation of mucus thrown off by an infected person while coughing, sneezing, loud speaking, etc.; it is also taken from dust similarly contaminated; handkerchiefs, soiled hands, milk, etc., may also be the means of conveyance. The bacilli may be taken in by the digestive tract and be carried to the lungs by the blood stream. The tonsils and retropharyngeal tissue may be the focus of infection, the cervical lymph nodes being next involved, and then the lungs.

4. *Calcification of arteries.*—"Calcified plates are frequently met with in the intima of the aorta and other large arteries as part of the change known as atheroma. It sometimes a more or less general calcification of the vessels, especially as a senile change, and is then frequently associated with other degenerative changes in the arterial walls. It is commonest in vessels of medium size, the arteries of the upper and lower extremities and of the brain being frequently affected. It may affect both internal and middle coats, often commencing in the muscle-cells of the latter. The calcareous particles, deposited from the vasa vasorum, make their appearance at first around and within the nucleus, and gradually accumulate until they fill the cell, which becomes converted into a small calcareous plate. The process may go on until the muscular coat is completely calcified; or it may be limited to isolated portions of the coat, giving rise to numerous irregularly distributed calcareous rings and plates, somewhat

suggestive of a piece of ipecacuanha root. These are best seen in vessels clarified and dried. From the muscular it may extend to the external and internal coats, until ultimately the vessel becomes calcified throughout. The vessel thus calcified loses its elasticity and contractility; its lumen is diminished, and it is transformed into a hard, rigid, brittle tube, or 'pipe-stem artery.' Such an artery is partially protected against dilatation, but is predisposed to rupture: in amputations great difficulty may be found in securing such vessels, as ligatures cut through them at once. The nutrition of parts supplied by them is more or less impaired, and general calcification of the arteries of the lower limb, therefore, predisposes to *senile gangrene*, inasmuch as it renders the vessels less able to adapt themselves to the varying requirements of the circulation. (Green's *Pathology.*)

5. *The Counting of bacteria*.—"Definite quantities of the material to be analyzed are mixed with gelatin or agar and poured into Petri plates. The exact dilutions of the suspected material must largely depend upon the number of germs which one expects to find in it. The plates, if prepared with gelatin, are allowed to develop at room temperature for twenty-four to forty-eight hours. If agar has been used, they are usually placed in the incubator at 37.5° C. At the end of this time, the colonies which have developed are enumerated. For this purpose, a Petri dish is placed upon a Wolffhügel plate. This plate consists of a disk or square of glass which is divided into small squares of one inch square centimeter each. Diagonal lines of these squares running at right angles to each other are subdivided into nine divisions each in order to facilitate counting when the colonies are unusually abundant. The Petri dish is placed upon the plate in such a way that the center of the dish corresponds to the center of the plate. The colonies in a definite number of squares are then counted. The greater the number of squares that are counted the more accurate the estimation will be. When the growth is so abundant that only a limited number of squares can be counted, these should be chosen as much as possible from different parts of the plate, and in practice one counts usually six squares in one direction and six at right angles to these, so as to preclude errors arising from unequal distribution. The final calculation is then made by ascertaining the average number of colonies contained in each square centimeter. If standard Petri dishes have been used, this is multiplied by 63.6, the number of squares in the area of the dish, and then by the dilution originally used.

"Thus if twelve squares have been counted with a total number of one hundred and forty-four colonies—the average for each square is twelve. Twelve times 63.6 is 763.2, which represents the total number of colonies in the plate. Now if 0.1 c.c. of the original material has been plated, this material may be assumed to have contained 10 × 763.2, or 7,632 bacteria to each cubic centimeter."—(Hiss and Zinsser's *Text-Book of Bacteriology.*)

6. *Hypertrophied prostate*.—"At first it retains its shape, then it becomes lobulated and irregular. The lateral lobes enlarge towards the rectum. The median lobe and the whole of the superior surface grow up into the bladder. A median constriction marks the attachment of the neck of the bladder, and separates the intravesical from the extravesical parts of the gland. The enlarged gland consists of either: (1) Excess of fibrous tissue: usual in the smallest specimens which cause symptoms; (2) Overgrowth of all the normal tissues: usual in the smooth medium-sized specimens; (3) Fibromyomatous tumors or fibroids: may form large masses; (4) Fibro-adenomata, *i.e.*, overgrowth of the glandular tissue: constitute the bulk of the largest specimens; (5) A well-marked laminated capsule consisting of layers of fibromuscular tissue surrounds the rest of the mass, and is continuous with the muscular walls of the bladder.

Changes in the urethra.—"Elongated from one to several inches. Curved with the convexity backwards. Tortuous from the pressure of enlarged lobules. Internal meatus may be distorted or blocked by the growth of the median lobe, or rarely held open by the same.

Changes in the bladder and kidneys.—"The bladder becomes first hypertrophied and then dilated, the muscular fasciculi being separated, and the mucous membrane pouched between the fasciculi. Cystitis occurs sooner or later. Hydronephrosis, pyonephrosis, or pyelonephritis may result from chronic retention and cystitis."—(Grove's *Synopsis of Surgery.*)

7. *Focal infection*.—"A local focus of infection may be the source of acute septicemia, but in addition a variety of chronic infections may arise with distant and important manifestations. The resulting infection may be either local or general. The importance and frequency of focal sepsis have been emphasized in recent years and it gives the clue to the etiology of many obscure conditions. . . . The organism most often concerned is some variety of streptococcus. . . . The local infection may be situated in many parts of the body; but in a majority the situation is in the mouth or tonsil. Investigation has shown the frequency of deep tonsillar infection, which may show no indication on the surface. . . . The lesions may be varied and situated in almost any part of the body. Perhaps the most frequent sites are the joints and fibrous tissues. Arthritis is common and many of the obscure pains, termed myalgia, neuritis, 'chronic and muscular rheumatism,' are really due to fibrositis secondary to a focal infection. Among other resulting lesions are endocarditis, myocarditis, gastric ulcer, cholecystitis, appendicitis and nephritis. The resulting disturbance is due to absorbed toxins or to bacteria which reach the blood stream or lymph and are carried to other parts."—From Osler and McCrae's *Practice of Medicine.*)

8. *Louis Pasteur* was a chemist and bacteriologist. He was born in 1822 and died in 1895. *His principal contributions to human medicine*, are: Discovery of the *Staphylococcus pyogenes* in boils, and of the *Streptococcus pyogenes* in puerperal septicemia; discovery of the bacillus of malignant edema; work on anthrax; discovery of preventive inoculation; work on hydrophobia.

9. *Typhoid vaccine* is a vaccine of killed typhoid bacilli which, when injected into the body, produces antibodies which protect the body against living typhoid baccili. The use of typhoid vaccines as a prophylactic measure against typhoid fever has been wonderfully successful in the army and also in civil life. Since the introduction of compulsory anti-typhoid vaccination in the United States army in 1910 there has been a steady, but decided, decline of typhoid. In 1913, there was only one case reported in 80,000 men. In the British army, the death rate from typhoid has been reduced 50 per cent.

10. "*Diphtheria* is primarily a local disease of the pharynx, of the larynx, of the nose, or of the skin. The bacillus lodges in the mucous membrane or skin, and produces a pseudomembrane. This consists of fibrinous exudation in the form of fine granular material or a fibrillar network, in which are embedded the epithelial cells and other tissue-elements and infiltrating leukocytes. The epithelial cells rapidly undergo coagulation-necrosis or granular degeneration, as do also the connective tissues when the process extends beneath the mucosa. The blood-vessels become obstructed by thrombosis or compression, and the tissue is therefore avascular. Nearly always the pseudomembrane thus formed is attached to the underlying tissues, and when removed a raw and bleeding surface is exposed. The depth of involvement, however, varies; sometimes the submucosa is soon involved; more often the disease is practically confined to the mucosa. The macroscopic appearance is that of a whitish, dirty-yellowish, or brownish membrane upon the mucous lining of the throat. This begins as one or several patches upon the tonsil, and spreads rapidly to the neighboring parts. In other situations the appearance is much the same. Inflammatory swelling beneath and around the diseased area is habitual. It is of great clinical importance to recognize that true diphtheria may occur in the form of typical follicular tonsillitis.

"*Internal* or *visceral lesions* may occur in the course of diphtheria or during convalescence. They are due to the action of the toxin, and not of the bacillus. Necrotic foci in the liver, showing advanced cellular degeneration of the cells with hyperchromatosis of the nuclei, and similar lesions of other organs, may be

seen in the body. Myocarditis and myocardial degeneration, renal degeneration and nephritis, and degeneration of the peripheral nerves and neuritis, may be met with."—(Stengel's *Text-Book of Pathology.*)

PRACTICE OF MEDICINE.

1. *Cerebrospinal meningitis* has an incubation period varying from a few hours to a week or ten days. The onset may be gradual or sudden (generally the latter), and is usually marked by a chill and rise of temperature. Headache, rigid neck, and hyperesthesia are constant; and vomiting, and mental, motor and sensory symptoms are often present. In fatal cases paralysis, coma, and convulsions have been observed. The *diagnostic factors* are: The presence of the headache, retracted and rigid neck, and hyperesthesia; vomiting, fever, and convulsions; lumbar puncture shows increased pressure in the spinal fluid and the presence of the *diplococcus intracellularis meningitidis*. The presence of Brudzinski's sign and Kernig's sign are also said to be diagnostic. *Treatment* includes the use of Flexner's serum (injected into the subarachnoid space after about 40 c.c. of the spinal fluid has been withdrawn). The patient is to be kept in a dark room, with his head elevated (but not flexed) and an ice bag applied to head and spine. Nutrient enemata may be required; both bowels and bladder need to be watched. Nervous symptoms may demand an opiate or chloral; urotropin is said to be of service.

2. ACUTE BRONCHITIS IN CHILDREN.—*Symptoms:* "The symptoms usually begin with a coryza, or follow an obstinate rhinitis or tracheitis. There is a hard, dry cough which soon becomes loose as more mucus is produced. The pulse and temperature are slightly elevated, rarely over 101° F. during the day, but may be a degree or two higher in the evening, while the respirations are always higher than normal. The child, as a rule, does not complain and may be quite willing to be about; infants, however, are often restless and irritable and vomiting may result from an attack of coughing. The stools are rarely normal, either constipation or loose stools being observed. It must be recollected that the sputum is swallowed by infants and children up to five years of age. The disease tends to recovery in from five days to a week. Severer forms are seen which are due to involvement of the smaller bronchi (formerly termed capillary bronchitis) in which the symptoms are more pronounced and there is some dyspnea. The pulse and respiratory ratio may be somewhat disturbed and a pneumonic process result from infection of the alveoli.

Treatment.—"Rest for the patient and fresh air are necessary requirements. A change to a different climate will often alone effect a cure. The bowels should be opened with a grain of calomel in divided doses or one or two drams of castor oil. The diet is to be restricted and water freely given. If the temperature is unduly high and is causing discomfort, an alcohol rub is indicated. The use of hot poultices and jackets are mentioned only to be condemned, and the same may be said of the so-called syrupy cough mixtures. If the secretions are persistently dry and the cough harassing, the Liq. ammonia anisatis in 3 to 5 drop doses in water to a child of five years or the aromatic spirits of ammonia in five to ten drop doses, diluted, is also effective. Do not give muriate of ammonia to children. If at night a sedative is necessary to allow the child to sleep, appropriate doses of any of the following drugs may be given: Codein, tincture opii camphorata, antipyrin, or sodium bromid.

"The room is to be kept well ventilated and the temperature not above 70° F. An enforced rest in bed with no further treatment than a free catharsis is often alone curative. If the child has adenoids and enlarged tonsils these should be removed at a later date to prevent subsequent attacks."—(Chapin and Pisek's *Diseases of Children.*)

3.

HYPERTROPHIC CIRRHOSIS.	CARCINOMA OF LIVER.
Absence of recognizable causes.	Hereditary history.
Occurs in young adults and in childhood.	Occurs usually after forty years of age.
Usually a primary affection.	Often occurs as a secondary growth.
Jaundice is slight unless grave symptoms develop; there is no cachexia.	Anemia is present, and also the development of a typical cachexia.
Paroxyms of pain. The case runs a slow course, usually lasting many years.	Pain more constant, with rapid emaciation. The case terminates usually within one year.
Enlargement is uniform.	The liver is irregularly enlarged, and contains umbilicated nodules.

—(Ander's *Practice of Medicine.*)

4. PLEURISY WITH EFFUSION	LOBAR PNEUMONIA
Onset marked by chilliness persisting for a few days.	Onset acute, with rigor, lasting one hour or longer.
Cough is irritating; no expectoration, or, if present, catarrhal in character.	Cough more marked, and accompanied by rusty or bloody, tenacious expectoration.
Sputum negative; tubercle bacilli rare.	Dense aggregations of pneumococci present.
Moderate fever of continuous type; declines by lysis.	Fever, 102° to 104° F.; falls by crisis.
Prostration moderate.	Prostration extreme.
Unilateral distention of the thorax.	Absent.
Countenance pale and anxious.	Mahogany-colored flush of cheeks.
Limited expansion at base of chest on the affected side.	Degree of expansion slightly, if at all, inhibited.
Tactile fremitus diminished or absent.	Increased over area of consolidation.
Interspaces bulging at base of chest.	Absent.
Percussion shows flatness, with great resistance to the plexiometer finger.	Dullness with less resistance, and sometimes a tympanitic note.
Diminished or absent breath-sounds over effusion the rule. Respiration murmur diffuse, distant, and generally unaccompanied by rales. Bronchial breathing may be present over the entire affected side of the chest.	Harsh bronchial breathing and presence of rales in first and third stages, unless a bronchus is plugged.
Friction sound heard in early and late stages.	No friction murmur; rales present.

(Anders and Boston's *Medical Diagnosis*).

5. *Diagnosis of typhoid fever* is based on (1) some characteristic signs and symptoms, such as the temperature curve, the rash, the enlarged spleen, slow pulse, leucopenia with relative lymphocytosis. None of these *alone* is diagnostic; but the combination is valuable. (2) The finding of the bacillus typhosus in the urine or blood is conclusive. The Widal reaction is positive in about 95 per cent. of typhoid cases.

Treatment of typhoid fever. The patient must be in bed, and no medicine given unless indicated. "Give no solid food, or that which would not readily pass through a fine sieve. Milk, if it agrees, albumin-water made from white of egg, beef tea, and chicken broth are the principal foods. Of late some authorities have advocated a light solid diet throughout, but nothing must be given that would increase the risk of perforation. The stools should be daily inspected. If undigested curd is found, milk is being given too often, or the gastric function is impaired. It may then be given with lime water or barley water. Beef tea should be sparingly used, lest it excite diarrhea. Alcohol is required mainly in the later stages, when the typhoid state has set in, and the heart is weak. Other stimulants are strychnine, ammonia, ether, etc.

"If the *diarrhea* becomes excessive give bismuth and opium, or lead acetate and morphia, or an enema of starch and opium. When the motions are very offensive intestinal antiseptics (calomel in small doses, salol, etc.), may be given. They are also useful in meteorism. If *constipation* be troublesome, give enemata. No purgative should be given after the first week. *Hemorrhage*—opium, lead acetate, or calcium lactate gr. xv every four hours, hypodermic injection of morphine or ergotin, ice-bag to the cecum. *Perforation.*—The main chance of recovery lies in early laparotomy and suture of the affected bowel. Every hour lost after the diagnosis is made, and the initial shock has passed off, increases the danger to life. Cases operated on within twenty-four hours may recover; later, recovery is very rare. In anticipation of operation, morphine may be given to relieve pain and diminish peristalsis. *Bed sores*—water-bed, cleanliness, stimulant and antiseptic lotions, dry dressings if the slough is large. High fever—quinine and cold baths. The antipyrin group is dangerous to the heart. The stools and urine must be carefully disinfected. During *convalescence* the diet must be increased with the utmost caution, and the possibility of relapse must always be remembered."—(Wheeler and Jack's *Handbook of Medicine.*)

6. *Complications of measles* are: Bronchitis, bronchopneumonia, laryngitis, diarrhea, convulsions, stomatitis, noma, otitis media, nephritis and endocarditis.

The *period of isolation* is from the beginning of the prodromal catarrhal symptoms until the cessation of the abnormal secretions from the mucous membrane—or from the commencement until the rash has disappeared for five days.

7. ERYSIPELAS. *Etiology:* The *streptococcus erysipelatis,* which gains admission through a wound or abrasion. *Treatment: Prophylaxis.*—Secure the asepsis of all wounds. All cases should be isolated to prevent the infection of others. *Local.*—In most cases all that is necessary is to apply lead, or lead and opium lotion. This has no curative action, but it relieves the stiffness and burning. Other applications, such as ichthyol, are, used, but do not hasten the termination of the process. A form of treatment which aims at getting ready a supply of phagocytes at a distance of 2 inches from the spreading margin is the most promising. The skin is irritated by free scarification, and the tissues then become infiltrated with leucocytes, which are ready to attack the cocci when they spread in this region. The part is kept covered with carbolic fomentations (1 in 40). *General.*—Good food and stimulants. The bowels should be kept acting by magnesium sulphate, and 2 to 4 grains of quinine with 15 minims of the tincture of perchloride of iron are generally given every four hours. Antistreptococcic serum sometimes is very useful, either injected or given by the rectum. The treatment of cellulo-cutaneous erysipelas is that of cellulitis."—(*Aids to Surgery.*)

The physician must be careful not to spread the infection; he should isolate the patient and his attendants, he should protect himself from infection, and disinfect himself, his hands, and his hair after attending the patient; he should also abstain from surgical operations and obstetrical cases while he is attending a case of erysipelas.

8. TREATMENT OF BRONCHIAL ASTHMA. "(1) *During the Attack.*—Remove any obvious cause of reflex irritation, such as overloading of the stomach. A brisk emetic often cuts an attack short; nitrites, especially nitrite of amyl, or chloroform may be inhaled. Belladonna, stramonium, and lobelia in combination with ammonia are useful remedies; the fumes of burnt niter papers, etc., are also recommended. A hypodermic injection of morphine may be needed; and pilocarpin or adrenalin may also be used hypodermically. The drug which has most claim to be regarded as specific is iodide of potassium. It should be given during the intervals and steadily persevered with. It is often successful, but as often fails, the disease being very refractory to treatment. (2) *During the Intervals.*—Change of air, careful diet, cod-liver oil, tonics, etc. A suitable climate must be found by experiment in each case. Such sources of reflex irritation as nasal disorders, gastro-intestinal irritation, uterine or urethral disease, must be sought for and removed. The diet must be light and non-stimulating, and the general health should be kept at the highest possible level." (Wheeler and Jack's *Handbook of Medicine*).

9. *Causes of vomiting in infants and young children.*—The acute febrile and infective diseases, meningitis, intracranial affections, acidosis, uremia, renal disease, intestinal obstruction, peritonitis, reflex causes (worms, teething, ear troubles), cardiac dilatation, heart failure, congenital hypertrophy of pylorus, spasm of pylorus, whooping cough, severe coughing in general, improper feeding, and dyspepsia.

10. *Symptoms of dementia præcox.*—"Many of the cases present some of the stigmata of degeneration, while some of them previous to the development of the disease have been bright. Others have presented peculiarities such as becoming delirious from slight provocation, convulsions in youth, susceptibility to alcohol, either the absence of sexual impulses or their early and unnatural development; eccentricities, precocious piety, seclusiveness, impulsiveness, moral instability, and weak-mindedness. Epileptiform or syncopal attacks may occur more or less frequently in the course of the disease; more rarely apoplectiform attacks, followed by a more or less permanent paralysis, occur as the first symptom of the trouble. Hysterical attacks also occur. Choreiform movements of the facial muscles, as wrinkling of the eyebrows, distortion of the mouth, rolling the eyes, "making faces," smacking the lips, sniffing, grunting, etc., are very characteristic. The deep reflexes are usually increased, as is also the mechanical irritability of the muscles and nerves. The pupils are usually dilated, and may be unequal. Hypalgesia, vasomotor disturbances, excessive secretion of saliva and sweat, irregular and scanty menstruation, vascular disturbances, subnormal temperature, anemia, either anorexia or voracious appetite, and in the early stages insomnia, and loss of weight, may be all present more or less frequently." (Potts' *Nervous and Mental Diseases*).

(*To be continued.*)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

SOAPS AND PROTEINS. By Dr. MARTIN H. FISCHER. 272 pages and 14 figures. Price, $4.00. Published by John Wiley & Sons, Inc., New York.

STUDIES IN DEFICIENCY DISEASE. By Dr. ROBERT MCGARRISON. 270 pages, illustrated. Published by the Oxford University Press, American Branch, New York.

BELLEVUE AND ALLIED HOSPITALS, CITY OF NEW YORK, Eighteenth Anual Report, January 1, 1919, to December 31, 1919. 107 pages with tables.

THE POCKET ANATOMY. By C. H. FAGGE. 313 pages. Price, $1.75. Published by William Wood & Company, New York.

FASTING AND MAN'S CORRECT DIET. By R. B. PEARSON. 153 pages. Price, $1.75. Published by the author, Chicago, Ill.

OPERATIVE SURGERY. By J. SHELTON HORSLEY 721 pages, 613 illustrations. Price, $10.00. Published by C. V. Mosby Company, St. Louis, Mo.

DIATHERMY By ELKIN P. CUMBERBATCH. 193 pages with 44 figures. Price, $6.00. Published by C. V. Mosby Company, St. Louis, Mo.

Medical History.

NEW BOOKS AND OLD.

XV.—THE LANCET.

BY JOHN RUHRÄH, M.D.,

BALTIMORE, MD.

IT is scarcely probable that Thomas Wakley had any idea what was to be the result of his venture into journalism when on October 5, 1823, he brought out the first number of the *Lancet*. Now that the centennial of this old vigorous medical journal is rapidly approaching, it may not be out of place to make some comments on it and give a brief historical account taken partly from a leaflet recently issued.

In the fourth number of the first volume of the *Asclepiad*, published in 1884, by Benjamin Ward Richardson, there is a delightful account of Thomas Wakley under the title of "A Great Medical Reformer." Richardson states that when he was in the vestibule of the Esculapian Temple, Wakley was one of the most striking figures within it, was one of the first to welcome the newcomer, to strengthen him in intention and inspire him with hope. Of this remarkable man who served so long as coroner for Middlesex and as member of Parliament from Finsbury, Richardson says:

> This man was not, like my Gilbert and Harvey, a discoverer in natural science; he was not, like my Keats, a poet. He had few of the qualities of any of those of "our great ones of the past," whose lives I wrote long ago. But in his way he was very great, very powerful, very much feared, and, withal, and as a consequence, very severely attacked by many, but by none more than by those who felt surest that he would never divine, by their manner and bearing toward him, from whom the offense came.
>
> To my young mind it was a new experience to see the behavior with which this man was treated, such merciless aspersion, such truckling servility, such cowardice, and often too from quarters where it was least expected. I remember talking to my good old friend, Dr. Robert Willis, on this subject, and saying that I had half a mind to leave a profession in which I was morally disheartened, and try my luck at the bar. "You will fare no better there," he replied, "if you try it, and you had better go on. As to the man you name, in whatever profession he had entered, he would have shared the same fortune and misfortune. In the Church he would have been a Pope or a martyr; in the Law a Lord Chancellor, or a reformer out of the recognized pale; in the Army a General or a rebel; in the Navy an Admiral or a corsair. In Medicine he has no scope for such extremes, but he is what he is there, a character quite unique, utterly fearless, resentful of all narrow abuses, and, according to his lights, honest as he is fearless and determined; a man who would crush an enemy as he would a wasp and treat a flatterer, whom he knew for such, as a born enemy; but who loves his friends and helps some, whom he thinks well of, much beyond their merits."

When the *Lancet* was started the condition of the medical profession in the United Kingdom was not all that might be desired. The members of the profession for the most part were not learned, held no social position, and quackery reigned supreme. Wakley believed that this was largely due to the selfishness of the leaders of the profession and to the manner in which the great medical corporations were conducted. The medical profession was divided into two classes, the leaders trying to keep down the rank and file as much as possible. Wakley was a member of the Royal College of Surgeons and one of the first things he did as an editor was to point out in no uncertain terms that the great corporations were not doing their duty in the matter of educating the students and that the material in the hospitals was not properly utilized for instruction. All this made a great stir and the leaders of the profession were violently opposed to him, but the humbler members of the profession took the other side. Week after week the conditions were ridiculed, and eventually the personal liberty of the editor was threatened and a parliamentary committee held to inquire into the charges brought by the *Lancet*. Why Wakley was not murdered for some of his onslaughts is hard to understand. If you will turn to some of the earlier numbers of the *Lancet* and read some of the letters and some of the statements you can get some idea of his method of stirring things up. An example taken almost at random gives some idea of his method. It is from a leading article bearing the heading "Mr. Abernethy and His Chancery Application."

> Now had they conducted the contest at all like honourable opponents, and fought only with recognized legitimate weapons, we should not have complained; it was natural that they should contend, and lustily, too, for the security of those "golden mites" which custom had, for so long a period, allotted to them. Therefore had the "Hole and Corner" people disputed every inch of ground in the most resolute manner, by an honourable mode of warfare, it would have betrayed weakness and petulance on our part, had we complained of it, or even alluded to it; indeed, we should rather have complimented them for the tenacious adherence with which they had defended the following enlightened maxim of their forefathers:
>
> "It is their duty, all the learned think,
> T' uphold the cause by which they eat and drink."
>
> Opposition we expected—hostility we anticipated—but certainly not of the description we have met with; it has been unmanly to the last degree; it has been grovelling, base, and vile; it really would appear that we are engaged in a conflict with the lowest reptiles, rather than with beings which had been bred and nurtured in the bosom of civilized society. Our opponents never meet us fairly, never candidly; they substitute falsehood for truth, calumny for argument, and reply to remarks on public utility by a scandalous and disgraceful attack on private character. Such cowardly, assassin-like conduct portrays the rottenness of their cause, and, at the same time, is the best proof of the stability and purity of ours. Of the misrepresentations we have just alluded to, there cannot be a more glaring one than the assertion, that Mr. Abernethy will sustain a pecuniary loss from the non-attendance of students, arising from the publication of his lectures. At the very moment when the "Hole and Corner" surgeons utter this sentence they know it to be false—radically, flagrantly false. We are here designated as the robbers, while in reality we are the robbed. This we will prove to the entire conviction of every unprejudiced—nay, every prejudiced mind.

The book reviews from the very beginning have the same character which they have to-day, only more so. The reviews show that the books considered have been actually read, a rare thing for a book reviewer of any kind to do, but the chief feature is the pitiless criticism, the showing up of mistakes of all kinds and making much of typographical errors from which no printing is exempt.

As the result of Wakley's activities a new charter was obtained from the College in 1844. He next took up the administration of the larger hospitals. Reforms were gradually accomplished by

vigorous and persistent fighting. The *Lancet* published the conditions in the hospitals, reports of what they regarded as malpractice. The relations of the students and the staff were also attacked and finally reformed and the selling of resident appointments by the medical staff was done away with. Many of the persons interested claimed they were being slandered and took their cases into the courts.

Another very important reform which Wakley accomplished was the registry of the duly qualified practitioners, thus enabling the public to differentiate between the trained medical men and the quacks. A bill for this purpose and for a system of medical education was introduced into the House of Commons in 1846 by the editor of the *Lancet*, but the opposition of corporations prevented its passage. Eventually, however, the socalled Warburton's Act of 1858 brought into existence the General Council of Medical Education and Registration of the United Kingdom.

In 1851 another revolutionary campaign was started, this time against the adulteration of foods and an Analytical Sanitary Commission was instituted to examine foods and drink and the results were so striking that a Parliamentary Committee was appointed in 1855 and as a result an act against the adulteration of food was passed in 1860. This has been followed since by other legislation along the same line.

Many other studies and reforms have been undertaken by the *Lancet*, among others, the clinical investigation of the causes of death under chloroform. This is one of the studies which led to the practical abandonment of chloroform as an anesthetic except in certain selected cases.

It is hardly necessary to catalogue the large number of studies made in the *Lancet* Laboratory, but they included a very large number of subjects ranging from the chemistry of lager beer to the soot fall of London.

During the war the paper devoted its energies to the medical interests of the Allies and ran with great success a relief fund for the Belgian Doctors and Pharmacists.

The *Lancet* claims to be largest and the oldest medical paper in the world, but the first claim doubtless could not be maintained for certainly as large if not larger journals are now published, but its independence is refreshing and its continuous efforts in its attempts to correct abuses and to better medical conditions, both for the profession and for the public have made for it a host of friends who will join in their congratulations on the centennial celebration of this justly renowned journal.

Rivière's Potion.—In his work entitled *Thérapeutique des vieux Maitres*, Dr. Fiessenger has given an account of Lazare Rivière, one of the best known of the old Montpellier physicians, whose biographer was the famous Astruc. Dr. Leclerc, in this connection, makes a short contribution on the subject of "Rivière's Potion" to *La Presse Médicale* for May 14, 1921, xxix, 39. Astruc relates that on December 6, 1610, he appeared before the Faculty of Medicine of Montpellier to solicit from them the "doctors' cap." He was judged too imperfectly educated to receive this honor, and his case was therefore postponed for a year. Greatly humiliated by this set-back, he nevertheless resumed his studies and on May 9 of the following year, when 22 years of age, he passed a brilliant examination and received his doctorate. Far from sleeping on his laurels, he worked unremittingly and in 1622 received a chair in the faculty with the assurance of the deanship in his turn, which came in due time. Up to his death in 1655 he was regarded as one of the leading practitioners of France, both at home and abroad. His *Praxis Medica*, written in elegant Latin, shows that he was a man of good common sense and a prudent and sagacious therapeutist. He was noted for his eclecticism and introduced the teaching of chemistry into the medical curriculum of the college. He was willing to make use of the remedies of irregular practitioners if they did good work, and it is possible that his well-known anti-emetic potion was of this origin. It consisted of two grams of "salt of absinthe" mixed with a teaspoonful of lemon juice and was used to relieve the nausae and vomiting of severe fevers. The "salt of absinthe" was simply the ash of that plant obtained by incineration and consisted chiefly of potassium carbonate; which, when mixed with the citric acid of the lemon juice, liberated carbonic acid. This remedy still persists in the French Codex as a double potion, one of sodium bicarbonate and the other of citric acid, which are ingested in rapid succession, a teaspoonful of each at a dose, and still recommended for nausea and vomiting.

The French Medical College at Pondichery.—This institution originated on paper as far back as 1823, but the organization and instruction was of the haphazard order. It was a matter of benevolence and philanthropy to teach young Hindoos the rudiments of medicine. Not until 1863 was there a formal movement begun in connection with the French Naval Medical Service to give instruction in sanitation and vaccination and to give qualifications to the natives after they had been duly examined. The standards of education were raised until in 1890 a five-year course was established, and in 1903 it became necessary for the medical student to possess the degree of bachelor of arts, or its equivalent. At present there are three degrees conferred. The first is that of native health officer, which seems equivalent to Doctor of Medicine. The second is the degree of public vaccinator. The candidate must be able to read, write, and speak French, and must have pursued the first two years of the medical course. He is entitled to practise minor surgery and is ostensibly an expert diagnostician of epidemic diseases and versed in their treatment. The third degree of diploma conferred is that of midwife. Although nothing is said on this point, it is clear that the term vaccinator means much more than immunizer against smallpox, for India is the home of bubonic plague and cholera, both of which are dealt with on a huge scale by preventive inoculation; and it is quite evident that the rôle of immunizer can be no sinecure. The foregoing account is taken from an abstract in *La Presse Médicale* for May 7, 1921, xxix, 37, of an article by Guérin in the *Bulletin de la Soc. de Pathologie exotique*.

SURGERY IN ADVANCED CANCER.

WITH ILLUSTRATIVE CASES.*

BY WILLIAM SEAMAN BAINBRIDGE, SC.D., M.D., C.M.

NEW YORK.

FOR many years an earnest effort has been made to discover the essential cause of cancer. Since the dawn of the present century there has been much research on the subject, but at this time we must admit that we are as much in ignorance of the basic cause of the disease as were the Egyptians or the early Greeks.

The whole subject of cancer is so shrouded in a maze of uncertainty, and lack of exact knowledge is so apparent, that one is tempted to be discouraged, and feel that the solution of the cancer problem is almost hopeless. However, if one scans the literature of the last one hundred and fifty years, he will find evidence of marked progress, for some of the diseases such as actinomycosis, tuberculosis, blastomycosis, and syphilis which formerly were included under the term "Cancer" are now recognized as entities and treated as such. Since the nature of these diseases has been determined only after years of intensive research, it seems hardly within reason to suppose that the end of differentiation has been reached, for that which is termed "Cancer" to-day may be, after all, a heterogeneous group of diseases. This thought should be a source of great encouragement and while we continue endeavoring to discover the essential cause or causes of cancer, we should endeavor to eliminate all known contributory factors in the causation of the disease.

It is a well accepted truth that surgery has a distinct place in precancerous conditions, in well developed cancer, and in many instances even in the advanced cases. The medical profession realizes that it assumes greater risks of recurrence and of operative mortality as it attacks more advanced stages of malignant disease. However, in the light of our present knowledge adequate surgery properly applied seems often to offer the best hope of relief and possible cure.

The object of this paper is to illustrate by case reports the value of radical surgical procedure in apparently inoperable, incurable, and irremovable cancer. For the sake of clearness, the paper has been divided roughly into four groups.

Group I. Surgery may remove complications of a non-malignant nature which mask the true limits of the cancer and, by removing these complications, prove the seemingly inoperable cancer to be entirely operable.

CASE A.—G. H.*; female; 54 years of age; married; 2 children. This patient consulted me November, 1909. She had been constipated for a long time and three years previously had developed a great deal of pain, gas, and general discomfort in the left side of the abdomen. Two years later mucus and blood, gradually increasing in volume, were discharged from the rectum. In May, 1909, exploratory laparotomy was performed by another surgeon, but so many adhesions were found that he considered the disease too far advanced for surgical interference.

On examination, November, 1909, I found intestinal stasis with marked cachexia, great loss of flesh and strength, and the lower pelvic colon almost totally obstructed by advanced cancer of the rectum. With the hope that the first operator had been mistaken in the extent of the disease and believing that, at all events, a colostomy would relieve the pressure and pain, exploratory laparotomy was performed. Adhesions from an old peritonitis following childbirth years before, were found and separated. Salpingo-oophorectomy for a diseased left ovary and tube was performed, and by the combined operation, using the vaginal outlet, two and one-half feet of intestine with mesorectum and mesosigmoid were removed and an end-to-end anastomosis was made between the bowel above and the remaining portion of the rectum below by a circular enterorrhaphy. Pathological examination proved this to be a case of adenocarcinoma of the rectum.

The patient had an uninterrupted recovery. She has gained 38 pounds in weight since the operation, has absolute control of her bowels and today, June, 1921, is a perfectly well woman.

Group II. Surgery may not remove the disease but may so confine it that the patient may live many years in comfort and comparative health.

CASE A.—T. J.; male; 53 years of age; married. Patient consulted me May, 1917. Two years previous he had an infection of the left lower jaw, and later a lump appeared on the same side of his neck. This lump was excised and proved to be a cyst. A few months later a discharge from the right ear developed. In January, 1917, the patient consulted a specialist for a painful condition of the throat and the physician pronounced the condition cancerous. The man then saw three other specialists, all of whom agreed with the first diagnosis. X-ray treatment was prescribed.

On examination May, 1917, I found a bulging mass, seemingly behind the soft palate on the right side, and an enlarged gland under the deep muscles near the angle of the right inferior maxilla. The growth seemed to involve the maxillary sinus on the right side and block the right posterior naris. There was a bad odor from the mouth. The patient was advised to have the glands in the neck removed and the blood vessels tied off, so as to retard the growth as far as possible. In May, 1917, all the lymphatic glands in the neck on the right side were removed, the external carotid and all its branches were tied off, with the ex-

*Preliminary report in *New York State Journal of Medicine*, October, 1913.

ception of the terminal branch. One month later the external carotid and all its branches on the left side were ligated. At the same time the lymphatic glands on the left side were removed. The primary growth was not interfered with. On pathological examination the gland was found to be a degenerated mixed tumor.

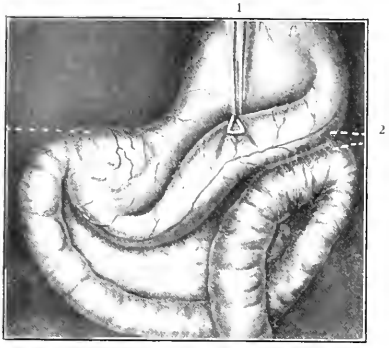

FIG. 1.—Group IV, Case A. 1. Forceps grasping stomach and bringing site of gastroenterostomy into view. 2. Opening from stomach into small bowel. 3. Area of carcinoma.

The patient had an uninterrupted recovery and in June, 1921, was in excellent condition. There was no evidence of disease in the neck. The nasal passages were no longer blocked and there was no discharge. During the war he took a very active part in Y. M. C. A. work and suffered no ill effects from long and strenuous hours.

CASE B.—O. S.; male, 55 years of age; married. This man consulted me July, 1917. His left tonsil had been troublesome for years, but three months previous to his visit it had grown much worse and three times during this period pieces of tonsil had been removed, once for diagnosis and twice for the elimination of the disease. On examination I found advanced carcinoma of the glands of the neck on the left side and of the soft palate, the mass extending towards the base of the tongue.

July, 1917, operation was performed for removal of the glands on the left side of the neck and ligation of the external carotid and its branches. This was done merely as a palliative measure, since the cancer was irremovable, the clinical diagnosis having been proved correct by pathological examination. No operation on the mouth was attempted.

The patient had an uninterrupted recovery and later was treated with radium. In October, 1917, he reported his general condition good and his neck in excellent shape, though the mass had not diminished materially in size.

In February, 1918, his physician in a distant city reported that the patient had developed ulcer of the stomach and peritonitis had set in, resulting in death.

CASE C.—W. S.; female; 45 years of age; married; children. In May, 1909, I was called in consultation for the patient who was in the menopause and suffering from a severe uterine hemorrhage. A number of physicians had seen the case and agreed that there was an irremovable cancer of the uterus, with a large cauliflower growth of the cervix, involving the whole upper part of the vagina and that nothing could be done except to give the patient morphine to relieve the pain. The pelvic glands were involved and the growth encroached upon the bladder.

Because of the patient's great suffering, both mental and physical, I described to the family the value of the lymphatic block and starvation ligature operation. Upon their urgent request a laparotomy was performed. The right and left ovarian arteries, the internal iliac arteries, and the sacra media were ligated and a large mass of lymph glands along the large vessels with both tubes and ovaries were removed. Radium gelatin was injected into the left side of the uterus, the broad ligament on that side being more involved than the right.

The patient had suffered marked pain in the left lumbar region as well as in the pelvis, and had had frequent and painful urination. When the abdomen was opened the left ureter was found blocked, and practically from the pelvic brim upward to the kidney it was dilated almost to the size of an adult thumb. The left kidney showed beginning hydronephrosis. After the starvation ligature and lymphatic block operation was performed, the ureter was separated very carefully from all points of pressure, and the bladder, which was empty, became full and the ureter was no longer distended. The pathologist's report was that of carcinoma uteri.

The patient had an uneventful recovery and gained more than twenty pounds in weight. She went to the country; was able to take long walks and had a comfortable summer. There was no hemorrhage and but a slight vaginal discharge which was easily controlled by ordinary douches. There was no return of pain in the left kidney region until just before the terminus late in the fall when an acute congestion of the kidneys, from pressure, evidently due to blocked ureters, caused an illness of a week, with death.

CASE D.—E. M.; female; 72 years of age; married. This patient consulted me March 1, 1909, for profuse and continued uterine hemorrhage. On examination, the cervix and vault of the vagina were found to be characteristically brawny. The patient was bedridden, in a grave condition, with uterine hemorrhage a constant danger and considered a hopeless case by those in attendance—with only a few days at most to live. There was cancer of the uterus with extensive involvment of the contiguous structures.

To control the fetid discharge and prevent hemorrhage, operation was performed and both internal iliac, both ovarian and the sacra media arteries were ligated.

The patient's convalescence was uneventful. She gradually regained strength, and was able to go about town in comparative comfort and without fear of uterine hemorrhage. On one occasion, after undue exercise, there was a slight venous oozing, but nothing sufficient to be of serious moment. Cachexia finally became marked, the patient failed and died more than ten months after operation.

CASE E.—C. P.; male; 69 years of age; married. Two years previous to consulting me the patient developed violent pain in the epigastrium and, later, passed blood streaked stools. An *x*-ray examination of the colon showed a constriction near the junction of

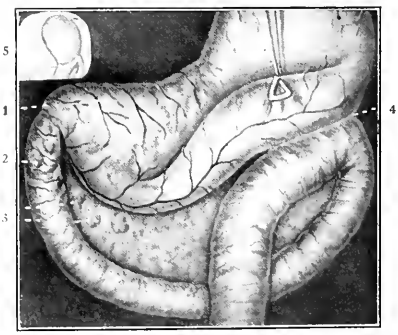

FIG. 2.—Group IV, Case A. 1. Area of involvement of gastric organ by carcinoma greatly increased. 2. Extension of malignant disease by continuity into first portion of duodenum. 3. Schematic drawing of what was left after operation.

the sigmoid with the rectum, about 5 cm. to 7 cm. in length and involving the entire wall of the intestine.

In May, 1917, a left inguinal colostomy, in two stages, was performed. Two months later an incision was made in the perineum preparatory to removal of the

rectum. The growth was found to be tightly adherent to the bladder and so high that it was impossible to remove it from below. An effort was then made to attack it from above but the mass in part proved irremovable. To retard the growth the blood vessels were ligated. The partition between the rectum and the urethra was found to be so necrotic that it was not possible to save it all and a plastic operation had to be done.

The patient's recovery was uneventful and three years after the operation, June, 1921, his physician reported that he had gained twenty-eight pounds in weight and was in excellent health.

Group III. Surgery may be advantageously employed to remove secondary conditions, save suffering and prolong life, without totally removing the growth.

Case A.—R. V.*; female; 29 years of age; married. This patient consulted me in May, 1907. She had had an exploratory laparotomy in another city and the diagnosis of irremovable round celled sarcoma made. The condition of the patient was such as to make this

Fig. 3.—Group IV, Case D. Ulcerating epithelioma before operation; dorsal view.

diagnosis seem improbable and I advised another exploratory laparotomy. On June 12, 1907, a second laparotomy was performed and papillomatous degeneration of the uterus, tubes, and ovaries was found, extending to the intestines and liver. A detached portion was removed for microscopic examination and the laboratory report was that of malignant adenopapilloma. Ten days later panhysterectomy was performed, a large papillomatous mass in the pelvis removed and a great amount of fluid evacuated.

The patient had an uneventful recovery. During the remaining ten years of life she had 18 laparotomies and 100 tappings under general anesthesia. About every six months it was necessary to open the abdomen and remove more of the papillomatous material, relieve the points of obstruction and a number of times excise portions of the large and small bowel. At a number of the operations oxygen was introduced into the abdomen by the method which I have described elsewhere (*Annals of Surgery*, March 1909.)

The fluid continued to collect in the abdomen, necessitating the many tappings. The patient remained in the hospital two or three weeks after each laparotomy and two or three hours after each paracentesis abdominalis. She had no cachexia, her bowels moved regularly, her color was good and her weight averaged

Fig. 4.—Group IV, Case D. Ulcerating epithelioma before operation; palmar view.

forty pounds more than at the time of her first operation. She was able to do her housework until within six weeks of her death and except for the discomfort experienced when her abdomen filled with fluid, she felt perfectly well.

Fig. 4.—Group IV, Case D. Appearance of the hand after the operation—ready for the plastic work.

The patient died in another city January, 1917, of intestinal obstruction and pneumonia. From the date of her first operation, June, 1907, she lived ten years in comparative comfort, even marrying a second husband during this period.

*Preliminary report in *N. Y. State Journal of Medicine*, October, 1913.

This case emphasizes the importance of differtiating between types of malignant neoplasms, and the fact, as stated at the beginning of this case, that surgery may be advantageously employed to remove secondary conditions—thus saving suffering and prolonging life.

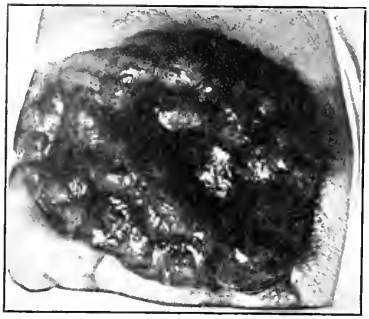

FIG. 6.—Group IV, Case E. Plaster cast showing the condition of advanced epithelioma of face and orbit.

Group IV. Radical surgery in advanced cases of carcinoma may totally remove the disease or permit the patient to go for many years without a recurrence.

CASE A.—J. H.; male; 49 years of age; married. This patient consulted me October, 1912, for continued nausea and the gradual loss of flesh and strength. *X*-ray pictures taken at this time showned carcinoma extending along the anterior wall of the stomach and including the greater curvature near the pylorus. There were in addition adhesions around the pylorus; the ascending and transverse colon were largely fused and there was an ileopelvic angulation.

November 1, 1912, a posterior gastroenterostomy was performed, but the condition of the patient, which was that of extreme anemia and emaciation, did not warrant the removal of the growth. After two months of forced feeding, the patient gained more than ten pounds, and a second operation was performed December 31, 1912. Between the first and second operations the cancer had increased two hundred per cent. and the disease had extended to the glands and head of the pancreas.

At the second operation an incision was made through the old abdominal scar. Three-quarters of the stomach, the upper half of the duodenum almost to the papule of Vater, with a portion of the head of the pancreas, and the large lymphatic glands in the neighborhood of the common duct, were removed. The free use of warm normal saline solution in the abdomen and submammary hypodermoclysis during the operation helped the patient to withstand shock. The pathological diagnosis was adenocarcinoma of the stomach. (Figs. 1 and 2.)

The patient was operated upon in December, 1912, and in May, 1921, he reported, as at intervals since the operation, for examination. He weighs 23 pounds more than he did in 1913, works every day and is able to eat and digest any kind of food without the least discomfort.

From all clinical signs, the *x*-ray pictures, the emaciation of the patient and the advanced state of cancer as seen at the first operation, there seemed very little in the history on which to base a hope of cure. But in spite of the unfavorable signs and conditions, the man has enjoyed eight years of absolutely normal existence and his present physical appearance would indicate that he may go on indefinitely with the hope that he is permanently cured.

A point of special interest in this case, referred to earlier in the report, is that during the two months between the first and second operations, when the patient was being built up for the more radical surgical procedure, the local condition extended very rapidly. It is a fine point of decision for the operator as to how far he should endeavor to improve the general condition of his patient before attacking the cancer.

CASE B.—M. A.; female; 34 years of age; single. This patient was referred to me in March, 1905. She had cancerous degeneration of the scar tissue of the right thigh, the result of burns many years earlier. Eight years previous to consulting me she was operated on for cancer at the same site and this operation was followed by many others, repeated recurrences taking place. At each operation the involvement was found to be deeper and finally the case was declared to be inoperable, as the disease had encroached upon the buttocks and groin.

On examination I found cancerous degeneration of scar tissue extending well down to the bone and involving all the soft parts underneath and around the large vessels on the inner side of the right thigh. The patient had lost much strength and flesh and showed great emaciation. I advised amputation at the hip joint, which was performed April, 1905. The difficulties of the operation were greatly increased by the fact that the disease had become so extensive as to leave nothing but short flaps of soft tissue available for covering the stump. Typical Wyeth amputation was done with the use of Wyeth pins. Pathological diagnosis was that of carcinoma of the femur and soft tissues.

The patient had an uneventful recovery and fifteen years later, November, 1920, reported herself free from recurrence and in excellent physical condition.

CASE C.—C. S.;* female; 44 years of age; married. This patient consulted me November, 1912, for profuse leucorrhea tinged with blood. This discharge had been

FIG. 7.—Group IV, Case E. After removal of the epithelioma; before plastic operation.

present three years and two surgeons whom the patient consulted diagnosed the condition as irremovable cancer of the uterus.

On examination I found evidence of advanced cervical carcinoma with extension into the body of the

*Preliminary Report in *New York State Journal of Medicine*, October, 1913.

uterus and apparent involvement of the broad ligaments and pelvic glands.

Operation was performed in November, 1910, panhysterectomy and vaginectomy, with double arterial ligation of internal iliacs, sacra media and ovarian arteries and removal of both ovaries and tubes, and the glands along the ureters from the receptacalum chyli to the obturator foramen on both sides. This is the operation for starvation ligature and lymphatic block which is described in the writer's book "The Cancer Problem," pages 385-395.

The pathological report was that of carcinoma of the cervix and uterus; chronic fibrocystic ovaries and hyperplasia of the pelvic glands.

The patient had an uneventful recovery and in May, 1921, over ten years after the operation, reported that she was in perfect health.

CASE D.—N. M.; female; 27 years of age; married. This patient consulted me November 16, 1914, for a fungoid growth, the size of a hen's egg, involving two fingers of the right hand and extending laterally to the back of the hand. The growth was ulcerated and there was enlargement of the epitrocheal gland on the right side. Three surgeons whom the patient consulted agreed that amputation of the arm was imperative.

Conservative operation was advised and on November 23, 1914, I removed the growth and part of the ring and little finger. Subsequent to operation there was some contraction of the little finger and the first phalanx of the third finger but this condition was improved later by plastic operation. (Figs. 3-5.)

May, 1921, the physician of the patient reported that she is in excellent health, that there is no recurrence of the cancer and the patient is able to use her hand without any discomfort.

CASE E.—B. G.;* female; 46 years of age; married. Eight years before consulting me the patient developed a small ulcer on the lower lid of the eye, following diphtheritic infection. The ulcer grew slowly for seven years but during the eighth year increased in size very rapidly.

When I first saw the patient, April, 1909, she was suffering from a large fungating epithelioma of the left orbit, involving the eyeball and extending to the dura mater.

FIG. 8.—Group IV, Case E.—Appearance of patient after plastic operation.

Operation was performed and the entire growth removed, including the contents of the orbit together with the inner wall down to the dura. The wound was then packed with gauze and allowed to granulate preparatory to plastic operation. A subsequent recurrence, with a leak of cerebral spinal fluid, necessitated a second operation, when an area of the dura, about the size of a ten cent piece, was removed. Plastic operation was performed at a later date.

The patient now wears a specially constructed glass over the eye. Her health is good, and, in the twelve

FIG. 9.—Group IV, Case E. Showing appearance of the patient wearing specially constructed spectacle. When the hair, which in the photograph is drawn back to show the extent of the scar, is allowed to cover the forehead, the patient is not unsightly.

years since the operation, there has been no recurrence of the condition. (Figs. 6-9.)

In order to give the patient the greatest chance in all these operations for cancer, the surgeon should first eliminate, as far as possible, any complicating factors present, including toxic ones arising from infections of the teeth, tonsils, sinuses or other source. If there is a site for absorption from external ulcerating cancer, the usual procedure for cleanliness should be observed. This also applies to mucous surfaces, such as the mouth and lower bowel. The gastrointestinal tract should have attention and, when possible, for a few days preceding operation the use of colonic irrigations, six to ten gallons a day, containing a dram of bicarbonate of soda to a pint of water, will prove very efficacious in eliminating poisons, hydrating the tissues and lessening acidosis. Preliminary to operation, all the usual safeguards against shock, such as morphine and atropin, are of value.

During operation the patient needs to be fortified for the severe surgical procedure, and hypodermoclysis, with normal saline or alkaline solution, may be given under the breasts as a support even before the patient shows evidence of the need of additional body fluid. If there is an abdominal section, normal saline solution can be advantageously employed, constantly pouring into the abdomen the warm fluid as it is taken up by the tissues. Thus the body heat is supported, the body fluid kept up, friction incident to handling the tissues is lessened, and the danger of postoperative adhesions is greatly diminished.

For the past ten years the author has uniformly

*Reported in part in "Campaign Against Cancer," *American Journal of Dermatology*, Vol. XV, No. 7, 1911.

employed the Murphy drip of one ounce glucose and two drams bicarbonate of soda to a quart of tap water, giving forty drops per minute until recovery from shock and a satisfactory functioning of the kidneys is obtained.

The victim of advanced cancer who confronts months of terrible suffering often will gladly accept the risk of fatality in order to secure relief. In facing these seemingly inoperable cases it is well to remember that radical surgery frequently *can* alleviate pain and *may*, in some instances, effect a permanent cure.

34 GRAMERCY PARK.

ANOTHER CASE OF ULCERATIVE COLITIS SUCCESSFULLY TREATED BY COLONIC IRRIGATIONS FROM ABOVE.

BY MAX EINHORN, M.D.,

NEW YORK,

PROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING PHYSICIAN TO THE LENOX HILL HOSPITAL.

A SHORT time ago I* reported a severe case of ulcerative colitis treated by injections into the large bowel, through the jointed intestinal tube, with beneficial results.

In as much as this mode of treatment is new and promises to be useful, I consider it of interest to describe a new case successfully treated by the same method.

The case is as follows:

Alfred S., age 20, volunteer soldier. Health had been good until September, 1919, when patient noticed bright red blood in stool. At first it appeared only occasionally, but soon was found with each bowel movement. He entered a hospital in Germany in latter part of September, 1919, and had a course of treatment lasting three weeks. For about three weeks following the hospital treatment the stool was free from blood. There were practically no other symptoms at this time. But the condition grew steadily worse until he came to this country in August, 1920. At this time there were present: anorexia, diarrhea, asthenia, and considerable loss of weight.

FIG. 1.—X-ray of patient Alfred S. one day after the third joint had been inserted. The two metal joints are visible in the intestine. Most of the small intestine is recognizable by the course of the tube and the metal capsule is situated in the ileum.

FIG. 2.—Two days after fourth joint had been inserted. All three joints are visible in the small intestine and the capsule deep in the ileum.

Previous to admission to the hospital the patient had been having 1 to 13 bowel movements daily, very often with tenesmus, and bright red blood persistently present. Had lost 16 pounds in weight from date of onset of disease to time of admission to the hospital.

Date of admission, December 7, 1920. Weight on admission, 132 pounds. Gastric analysis: HCL=50; total acidity=75; blood, negative. Rectal injections of 10 per cent gelatin (nocturnal) given from December 8 to 15, inclusive. Tannin-agar was given 1 dram t.i.d. Proctoscopic examination revealed inflamed ulcerative areas extending down to within 4½ inches of the anus. On December 13 the first section of the intestinal tube given; on the 14th the second part was attached; on the 15th the third part was attached, and on the 17th the fourth part was attached.

Calcium carbonate 0.5 to 1000 c.c. of water per drip through the tube twice a day was started on December 14. On the following day the *x*-ray showed the tip of the tube in the coils of the small bowel. On December 15 the following was given by injections:

R

Myrtle extract
Aq. distil. .....āāʒii ss
Starch .....ʒi

This rectal injection was given in place of the gelatine.

On December 16, 1920, *x*-ray shows the capsule of tube in the ileum (Fig. 1). December 19, 1920, *x*-ray shows tip of tube well in coils of small bowel (Fig. 2). On December 20, 22 and 24 the *x*-ray shows the tip of the tube at the same place (Ileocecal junction) in all three pictures (Fig. 3, 4, 5). On December 24 calcium carbonate 1.0 to 1,500 c.c. of water b.i.d. per tube

*Max Einhorn: A New Intestinal Tube with Remarks on its Use in a Case of Ulcerative Colitis. *Am. Journal of Med. Sciences*, April, 1921.

and ichthyol 15 drops in latter part of the drip.

Persistent examination of stool shows no parasites or amebas. Blood is present constantly. From December 25 to January 2, inclusive, two ounces of a 1 per cent solution of mercurochrome (220) was injected into the tube slowly in the middle of the day. Calcium carbonate solution was used morning and night. On January 1, 1921, one section of the tube was removed, and on January 3 the whole tube was removed through the mouth.

FIG. 3.—Same patient, one day later. Capsule end of the tube is situated in the cecum.

During the last week of treatment the stools were formed, patient having not more than three evacuations and usually but one daily. Blood was present in ever decreasing amounts. The patient felt better, the appetite was better, and he was generally improved. 1=3=21.—His weight was 130 pounds on January 3, and 153 pounds on January 22.

Since leaving the hospital patient has gained 23 pounds. Has one formed movement daily and no blood.

Remarks.—The case detailed above presented a very severe ulcerative lesion of the colon not yielding to any of the usual modes of treatment. Strict dietary régimes and rigorous medicinal measures applied in hospitals here and abroad proved of no benefit. Our efforts, likewise, were at first of no avail.

It appeared that this was a case in which a colostomy for direct flushings of the colon from above would be required. Instead of the operation, as in the first case described, the jointed intestinal tube was used, in order to accomplish the same result, namely, irrigation of the large bowel with various medicaments from above.

This, indeed, accomplished a cure. As detailed above, mercurochrome, 60 c.c. of a 1 per cent. solution, was instilled daily through the tube as soon as the latter had reached the cecum; while a solution of calcium carbonate (0.5; 1000) was instilled twice daily in quantities of a quart or a quart and a half at a time as soon as the tube had reached the small intestine. This was continued all the time until the tube had been withdrawn. The patient was nourished in the usual way by the mouth. The diet did not deviate from the usual antidiarrheic regime.

The appended *x*-ray photographs show the position of the tube, at first in the duodenum, and ultimately in the cecum. In as much as the entire colon had to be treated, no more joints had been added to the tube, since that spot (the cecum) had been reached.

While in my first case (*loc. cit.*) the tube after completing the course of the treatment was allowed to pass through the rectum, in the case reported it was withdrawn by the mouth.

Encountering quite some resistance in pulling the tube up, it was considered wise to accomplish it, not all at once, but in two sittings. Accordingly but one distal joint was pulled up, and unscrewed, while the remaining joints were left in the intestine for another day. Then the other three intestinal tube joints were withdrawn gently in a few minutes, not causing any pain or discomfort.

As above stated, the patient gained twenty-three pounds in about two months following the treatment and has remained perfectly well ever since. The two cases reported show the value of the intestinal tube as a therapeutic agent. They also clearly demonstrate that the removal of the tube can be accomplished without difficulty either by letting it pass through the rectum or by withdrawal through the mouth. It is, of course, understood that whenever there is suspicion of some obstruction within the intestine the tube will have to be pulled up through the mouth. In this instance, especially when there is much resistance encoun-

FIG. 4.—After four days and filling up the tube with a 2% bromide of sodium solution. The capsule is visible in the cecum and the course of the entire small intestine is clearly discernible.

tered when withdrawing the tube, it is best to perform this act in two sittings, first disengaging one joint, leaving the other tube joints in the alimentary tract for another day, when the rest is removed. The procedure is in this way made more comfortable for the patient.

20 East Sixty-third Street.

CLINICAL CALORIMETRY.*

By CHARLES FRANK MORSMAN, M.D.,

SPOKANE, WASH.

THE main facts of basal metabolism which we must always have in mind when we diagnose a case of hyperthyroidism or one of hypothyroidism and when we decide upon a plan of treatment for the case under consideration, have been known for a quarter of a century. But we have been unable to apply our knowledge, except in a few favored institutions, since the apparatus used in estimating it has been too cumbersome, too expensive, and too difficult of application.

Clinical calorimetry has been of slow but gradual growth and is based upon scientific facts. There have been none of the spectacular and unscientific advances and biased empiricisms in this branch of medicine as unfortunately the medical profession has witnessed in some of the other branches of our dignified calling. There is a striking similarity between clinical calorimetry and calorimetry used in determining the heat value of food and fuel. In the latter the chemist determines the caloric value of the material under consideration by placing a definite quantity in a cylinder supplied with an excess of oxygen, which is immersed in a definite quantity of water, and burns it by means of a glowing platinum wire which is heated by an electric current. The rise of temperature in the water surrounding the cylinder is determined by the thermometer, and from this is easily determined the quantity of heat given off by the oxidation process. In the former a chamber large enough to hold the man or animal under study is constructed. It is surrounded with water jackets and arrangements made to supply the subject with oxygen.

Pettenkofer is given credit for having perfected an apparatus for the study of metabolism by measuring heat radiation, as far back as 1862. In 1892 Isaac Ott used a simple apparatus of this type in the study of a man who was ill of malaria. However, we must give the Russians the credit for making the earliest elaborate studies of metabolism. Their reports were buried in obscure journals and they did not realize the importance of complete rest on the part of the subject under study.

It was not until 1908 that a real foundation for the scientific study of metabolism began to assume definite form. Since that time our knowledge in this branch of science has increased many fold. Atwater, Benedict, Lusk, Allen, and many others have made many studies in this field. They employed the apparatus of Pettenkofer or its modifications. This method is known as direct calorimetry. The reader is referred to the article by Eugene F. DuBois in the first volume of Oxford Medicine, page 379, which is a most excellent review of the important facts of the science of metabolism.

When Benedict announced, in the May 16, 1918, number of the *Boston Medical and Surgical Journal*, his apparatus which is now called the Benedict Portable Respiration Apparatus, for the estimation of oxygen consumption, he placed within the grasp of the entire medical profession a practical means by which basal metabolism may be accurately determined by indirect calorimetry. Since this apparatus has been placed on the market at a reasonable price, the work is being rapidly taken up in various parts of the country.

Benedict and his co-workers in the Nutrition Laboratory of the Carnegie Institution of Washington at Boston, are working almost entirely upon normals, both adults and children. Various other workers are devoting their time to the study of abnormals. Among these men may be mentioned DuBois of New York and McCaskey of Fort Wayne. DuBois and others have studied metabolism in goiter, in diabetes, and in other disturbances of health and he has given us an ingenious chart, which may be found in part 2 of the June 15, 1916, issue of the *Archives of Internal Medicine*, from which we may readily determine the body surface in square meters. McCaskey has studied this new method in its application to clinical practice and his three articles which appeared in the *Journal of the American Medical Association* of July 26, 1919, and April 3, 1920, and in the October 11, 1919, number of the *New York Medical Journal* are very interesting and instructive.†

Benedict took advantage of the fact that the surface radiation from the animal body may be accurately determined by measuring its oxygen consumption. His apparatus consists of a spirometer, a motor and blower to produce a constant circulation in the machine, a breathing appliance, a thermometer, and a jar of soda lime to take up the carbon dioxide given off by the patient.

In its application, the patient fasts for fourteen hours and then presents herself at the laboratory where she is weighed and measured for height, after which she is put at complete rest, lying on a couch, for thirty minutes, before the test is applied. Then she is asked to breathe from and into the apparatus for a period of five minutes to accustom her to its application. After a rest of ten or fifteen minutes, the test is again applied for a period of ten minutes by stop watch. The amount of oxygen which she has consumed in this application is noted and the volume is corrected to zero centigrade and to sea level. A third application is made as a check. The volume per hour corrected as to volume is calculated, and we must remember that each liter of oxygen consumed represents 4.825 calories of body surface radiation, and knowing our patient's weight in kilograms and height in centimeters, we have her surface area in square meters from the DuBois chart. We must remember that the average for women is 36.9 calories of surface radiation per square meter per hour and for men the average is 39.7 calories per square meter per hour.

*Read before The Spokane Academy of Medicine, November 11, 1920, and the Spokane County Medical Society, April 14, 1921.

†McCaskey's paper, Basal Metabolism Determinations with the Original Portable Benedict Apparatus, etc., appeared in the *Jour. A. M. A.*, lxxvi, April 9, 1921, since this article was written.

Two new apparatus for the estimation of basal metabolism have been described. In the *Journal A.M.A.* of August 21, 1920, Jones describes his apparatus, and Benedict and Collins describe their apparatus in the *Boston Medical and Surgical Journal* of October 14, 1920. I have seen neither of these apparatus. From the cuts and descriptions I have seen of them, I should say that the new instruments are more truly portable than Benedict's original apparatus.

It is very difficult to say just what variation from the average oxygen consumption may be admitted to be within normal limits. Heretofore, the limits have been conceded to be ten per cent. below and ten per cent. above the average, but in the light of present knowledge it would appear that it is necessary to extend these limits somewhat. Hendry, Carpenter and Emmes in the September 4, 1919, issue of the *Boston Medical and Surgical Journal*, showed in a study of seventeen presumably healthy Harvard students, two whose oxygen consumption remained persistently 14 per cent. below the average, and one who persistently consumed 11.5 per cent. above the average. In Benedict's communication in the March 4, 1920, issue of the *Boston Medical and Surgical Journal*, he warns us in italics that "There is no inflexible standard for normal metabolism for any given age, weight, height, or sex from which all normal individuals never vary."

In my own work, I consider that the metabolic rate of a given patient is normal when that individual's oxygen consumption falls within 12 per cent. above to 12 per cent. below the average. It must be remembered that the metabolic rate is but one point to be considered in diagnosis and as a basis for the determination of a plan of treatment. The metabolic rate must be checked by other laboratory findings, by physical examination, and by objective and subjective symptoms. It is evident that the more facts one has under consideration in a given case, the more nearly correct will be one's judgment in diagnosis, prognosis, and treatment.

By basal metabolism is meant that minimal amount of cell activity necessarily the result of the continuous organic functions of respiration, circulation and secretion. In the practical application of these studies we test out especially hyper- and hypofunction of the thyroid gland. In the various disturbances in which nutrition is involved, as for example in the anemias and diabetes, basal metabolism has proven of interest but of very little practical value.

Eugene F. DuBois says, in the "Medical Clinics of North America" of January, 1919: "Granting the value of the test (measurement of the basal metabolism) is it practicable? Calorimeters are out of the question except in a few laboratories. On the other hand, the simpler forms of apparatus for determining the basal metabolism are comparatively reasonable in cost, and fairly easy to operate. They are much less expensive than an electrocardiograph, and the technic is not so difficult. Still, there are many pitfalls waiting for the careless investigator, and it is advisable that anyone who starts to measure the total metabolism should begin with a series of normal controls."

"'But why,' says the practitioner, 'should I, who have seen hundreds of cases, go to all this trouble when I can perfectly well tell from the clinical aspect whether or not the metabolic rate is increased?' Such guessing is very common, quite fascinating, and not risky for one's reputation unless the results are checked. On the other hand, those clinicians who have checked up their guesses in two or three hundred experiments realize the frequency of their errors, especially in atypical cases, and are not surprised if they do not come within forty per cent. of the true figure."

Perhaps one may add that it is not absolutely necessary to do blood counts, uranalyses, or gastric analyses, if one is careless and does not desire to practice modern medicine. I know one practitioner of medicine who scorns to use the blood pressure apparatus and boasts that he can determine the blood pressure accurately enough for clinical purposes by palpating the radial artery. If one wishes to give his patients the best there is in medicine, he will freely use the proven laboratory methods which make for better diagnoses.

In the article just mentioned, the author draws these conclusions: "The diagnostician who interprets the basal metabolism intelligently will be able to determine the degree of thyroid activity. The surgeon who operates on thyroid patients will find that the basal metabolism is of a great help in following his results. He will also find that in many cases a fifteen-minute test with the respiration apparatus will save the patient a needless operation."

Means, in the *Boston Medical and Surgical Journal* of June 15, 1916, says, under the title of "Studies of the Basal Metabolism in Diseases, and their Importance in Clinical Medicine":

"In conclusion I should like to emphasize the following points: (1) Basal metabolism can be readily studied in a hospital clinic with comparatively inexpensive apparatus. (2) The normal basal metabolism is a fairly constant affair, and hence wide variations from it in disease are of interest to the clinician. (3) A marked rise occurs in hyperthyroidism. (4) A marked fall occurs in hypothyroidism. (5) In regard to hyperthyroidism it seems probable that the basal metabolism furnishes (*a*) The best index as to the severity of the disease, hence is a quantitative means of following the course and of judging of the effectiveness of treatment: (*b*) A valuable aid in differential diagnosis. 6) Enormous grades of obesity are possible in the presence of a normal metabolism. (7) When a reduction in the metabolism was found in obese subjects, there was also clinical evidence of defective internal secretion. (8) A clearer conception of the food requirements in disease is furnished by the basal metabolism than any other factor."

McCaskey says, in the April 3, 1920, number of the *Journal A.M.A.* that the routine determinations of basal metabolism are worth while in two groups of cases:

"1) In all cases of definite goiter and especially if associated with health disturbances to ascertain the degree, if any, of its toxicity. (2) In a large group of cases either with or without goiter, with symptoms resembling either closely or remotely those of thyrotoxicosis." In this last group he includes psychoneurotic disturbances, tachycardia, bradycardia, cardiac myasthenias, certain arrhythmias, fine tremors, hyperhidrosis, hypo-

hidrosis, general debility, loss of weight, and slight temperature disturbances.

The metabolic rate may be used as a basis for the determination of the plan of treatment in Graves disease. Sistrunk of the Mayo clinic in the issue of January 21, 1920, *Journal A.M.A.*, informs us that a very careful selection is made of the type of operation for patients with a rate above plus 40 per cent. They hesitate to perform a primary thyroidectomy on a patient whose metabolic rate is 60 to 70 per cent. above normal. In those acute cases primary ligations of the two superior thyroid poles are done a week apart to prepare the patient for the major operation. The result of thyroidectomy may be checked by determining the metabolic rate. We are able to diagnose hyperthyroidism, determine the status of the case in reference to operation, and finally to check the result of operation by metabolic rating.

In going over the literature relative to metabolic studies, one is struck by the comparative lack of reference to hypothyroidism in its various phases. There is no doubt that this condition is much more common than is generally acknowledged. Many of the cases of so-called neurasthenia fall within this group. Heretofore such cases have not been given adequate attention by the medical profession and they have fallen en masse into the hands of the various cults of uneducated, unscrupulous, counterfeit physicians. It is not well to call every case we do not understand, neurotic or asthenic or by some other indefinite term which is merely a confession of lack of thoroughness. Every obscure case should be studied fully and carefully, and in consequence one will be surprised by the number of satisfied patients he will add to his list.

McCaskey reported eight cases in the April 3, 1920, issue of the *Journal A.M.A.* Three of these are cases of hypothyroidism. Else reported three cases, one of which is hypothyroidism, in the July, 1920, issue of *Northwest Medicine*.

I wish to report four cases from my own list, including two of hypothyroidism:

Case I.—L. K., female, age 27, married, housewife. Family history is of no interest except that her father is extremely emotional and has an ungovernable temper, and a sister is given to periods of mental depression.

Personal History.—Had tonsillitis during childhood. Has not had arthritis. At the age of 20 began to feel listless and tired, especially after meals. Lost weight rapidly. Was married at 23. Child was born at age of 24. At age of 25 had lacerated perineum repaired and appendix and tonsils removed. At time of examination patient was very despondent and believed that nothing could be done for her.

Examination.—Patient very emaciated, weight 86.5 pounds; skin rough, pulse 62, blood pressure 70-100.

Blood Examination: normal. Uranalysis: normal. Test meals: normal.

Basal metabolism: minus 23 per cent

Diagnosis: Hypothyroidism

Treatment: Dietetic and ¼ gr. thyroid ext. t.i.d. Three months after treatment was instituted, patient declared she felt entirely well and her weight was 110¾ pounds. Two months later her weight was 119½ pounds.

Case II.—A. L. J., female, age 49, married, housewife. Chief complaints were of migraine and eczema.

The family history is uninteresting except that one sister has goiter.

Personal history shows that as a child she was constipated and often was sick with "bilious attacks." She was not a robust child. She had tonsillitis frequently. Menses began at the age of twelve, and were regular and very often painful. Periodical headaches began at the age of twenty and occurred at the menstrual period. Headache with vomiting occasionally occurred at irregular times. Patient attended college and worked hard to complete her course in music, and graduated in 1896. She afterward taught music in large classes until 1901 when she was married. All of these years she had headaches with vomiting. These occurred frequently. Patient has not menstruated for three years, and still the headaches occur at rather more frequent intervals than formerly. The patient has always been very fond of sweets. She has always been depressed after meals. She had a "nervous breakdown" in 1905 and suffered a similar attack in 1914. She has never been pregnant. Physical examination: Height 5 ft. 8 inches; weight 117 pounds; skin rough and eczematous; some teeth missing, no palpable glands. Romberg is negative. Pupils respond to light and accommodation. Deep reflexes subnormal. Heart is normal. Pulse, 70; blood pressure, 70-100. Blood examination shows hemoglobin 80, R. B. C. 4,790,000, W. B. C. 5,000. Gastric analysis gives the following facts: the motor meal returned 20 c.c. of clear, slightly greenish fluid, no food particles, total acidity 34 degrees, free HCl, 26. The Ewald meal was withdrawn at the end of the 45 minute period and 50 c.c. obtained. Total acidity, 58, free HCl, 38, combined 15, organic acid and acid salts 5. Uranalysis showed a normal urine.

Alimentary glycemia test showed fasting blood with a sugar content .086 per cent. at the end of the first hour after the ingestion of 1.75 grams of glucose per kgm. of body weight, .10 per cent.; second hour, .10 per cent.; the third hour, .15 per cent.; fourth hour, .18 per cent. Sugar did not show in hourly samples of urine.

Test by Benedict's apparatus showed a basal metabolic rate of minus 20 per cent.

Roentgen examination of gastrointestinal tract showed incompetent ileocecal valve, slight gastroenteroptosis, and extreme stasis of the large bowel. Patient still retained some of the barium at the end of 123 hours. Diagnosis: Gastroenteroptosis, colonic stasis, hypothyroidism. Treatment: Patient was put to bed for two weeks, suitable diet was instituted, and thyroid extract ¼ gr. t. i. d. was given. The thyroid extract was kept up for six months. Patient had two headaches after treatment was begun. This is written eight months after treatment was instituted. Patient now weighs 140 pounds, her eczema has entirely disappeared, she had not had a headache for six months, and is in better health than she had been for thirty years.

Case III.—K. R., male, age 19, student. Chief complaints were of rapid heart, distress after meals, insomnia, and constipation.

Family history: Father is "nervous," mother had a "nervous breakdown" ten years ago, one brother died at the age of 18 of some obscure liver condition.

Personal history: Was well as a child. At the age of 12 suffered a fracture of the arm as the result of falling from a horse. About a month after this accident patient became very nervous. Was not able to attend school for two years. He was able to do no work until three years ago because of rapid heart action. Patient felt well from January, 1917, to January, 1920, when he was ill with influenza. He was confined to his bed for nine days then hurried home to the death bed of his brother. Since that time patient has been introspective and irritable. This condition has grown rapidly worse lately. Patient says he feels "unreal." He dreads to begin an undertaking because of fear of result upon health.

Stomach symptoms: During the period of illness following fracture the patient suffered from attacks of abdominal pain which were always accompanied by much intestinal gas. This disturbance disappeared during the three years of good health. In February, 1920, the stomach began to give trouble again. Now there is much gas and a "full" sensation after the ingestion of food. There is no pain. There is complete anorexia. There is no vomiting or headache. There is much "heartburn." Constipation is obstinate.

Physical examination: Patient is fairly well nourished. Skin is soft and pliable. There are no palpable

glands. Thyroid is not palpable. Tongue protrudes in the median line. Tonsils appear normal. Teeth in fair condition. The hair is abundant. Heart outline is normal. Heart sounds are normal. Pulse 122 and after an hour's rest on a couch the rate is 105. Blood pressure 126-88. Chest examination gives no abnormal lung findings. Abdominal examination reveals only a tender area upon deep pressure 5 cm. above umbilicus. Romberg negative, deep reflexes normal. Pupils respond to light and accommodation; eye signs are all negative. Arm extended with fingers widely separated shows tremor.

Laboratory tests: Uranalysis normal, gastric analysis, motor meal (fasting stomach) free HCl 66, total acidity 116. Ewald meal: Free HCl 60, total acidity 88. Blood examination: Hemoglobin 90, R. B. C. 5,000,000, W. B. C. 6,400. Rate of basal metabolism, plus 23 per cent. Wassermann positive to three antigens. Roentgen examination showed hyperperistalsis of the stomach and small intestine and colonic stasis.

Diagnosis: Hereditary syphilis and mild hyperthyroidism.

Treatment: The patient is now undergoing antisyphilitic treatment.

Case IV.—N. H. S., female, widow, aged 46; embalmer. Chief complaint is tumor of the neck. Family history contains no striking facts. Personal history: Was well as a child and young woman. Sixteen years ago, shortly after birth of a child, a swelling of the neck was noticed. Tincture of iodine was applied for about a month. Twelve years ago after childbirth the tumor increased in size. About three years ago began to have increased heart action, which subsided after two years, and has not been noticed lately. About one year ago friends noticed that her eyes began to be prominent. Appetite is normal. There is some insomnia and some nervousness. There is no headache. Some vertigo at times. In February, 1920, all the teeth were extracted and double plates were obtained in June, 1920. Patient has gained some weight in the past six months.

Physical examination: Patient is well nourished. Skin is generally soft and pliable, though there are some rough areas. Tongue protrudes in median line. Tonsils are in place and appear normal. Patient has no teeth, and gums are in good condition. On the anterior aspect of the neck on the left of the trachea there is a tumor extending upward 4 cm. from the clavicle and 4 cm. laterally. Tumor is fairly tense, but responds to pressure and moves with swallowing. There are no palpable glands. There is no tremor. The eyes appear somewhat prominent. Temperature is 98.2°, pulse 78. Heart outline normal. Heart sounds normal. Blood pressure 110-80. Chest examination reveals no abnormal condition of lungs. Romberg is negative. Deep reflexes subnormal. Pupils respond to light and accommodation. The eye signs of Möbius, Stellwag and Von Grafe are all negative. Uranalysis reveals a normal urine. The metabolic rate is minus 14 per cent. Blood examination, R. B. C. 4,500,000; W. B. C., 6400; hemoglobin, 90; stained smear shows no abnormalities. Roentgen examination of heart at two meters shows normal measurements. Wassermann test is negative. Diagnosis: Cyst of thyroid. Case referred to Dr. A. A. Matthews of Spokane, who removed a cyst from the thyroid on June 28, 1920. Patient made an uneventful recovery.

Résumé—1. Clinical calorimetry is now within the reach of all.

2. Clinical calorimetry is based upon scientific facts.

3. Basal metabolism rating is entirely dependable if done carefully.

4. Clinically, metabolic rating is applicable to disturbances of the thyroid gland and in conditions simulating those disturbances.

5. Clinical calorimetry is an exact laboratory procedure and may be profitably added to our diagnostic armamentarium.

6. Four case reports are here given, two of which are of cases of hypothyroidism.

THE ACTION OF RADIUM ON TUMORS OF THE BONE.

WITH A REPORT OF TWO CASES.

By ISAAC LEVIN, M.D.,

NEW YORK,

Assistant Physician in Cancer Research, New York University and Bellevue Hospital Medical College; Chief of the Department of Cancer Research of Montefiore Home; Chief of the Radiotherapy Division of St. Rose Hospital.

Processes of repair, inflammation, or tumor formation, are accompanied, as a rule, by a reaction of the adjoining normal tissues of the organism. This reaction is either of a regressive nature and consists in the destruction of the normal tissue and its replacement by lymphoid or tumor cells, or it is progressive and manifests itself in the formation of a connective tissue stroma, a fibrous capsule or a scar.

The difference between the mechanism of reaction against injury of bone tissue and all other tissues consists in the fact that the former possesses special cells for both the regressive (osteoclasts) and progressive (osteoblasts) reactions. The regressive reaction of the bone tissue, osteoporosis, or destruction of the bone, is undoubtedly identical with the destruction of all types of normal tissues adjoining a local inflammatory process or a growing tumor. Osteosclerosis, or bone formation, on the other hand, presents an attempt by the organism to heal or overcome the pathological process, or to repair the injury caused by the loss of the bone. The two reactive processes, the osteoporosis, or destruction of the bone, and the osteosclerosis, the new bone formation, predominate the pathological picture to such an extent that it occasionally becomes difficult to distinguish the underlying clinical condition.

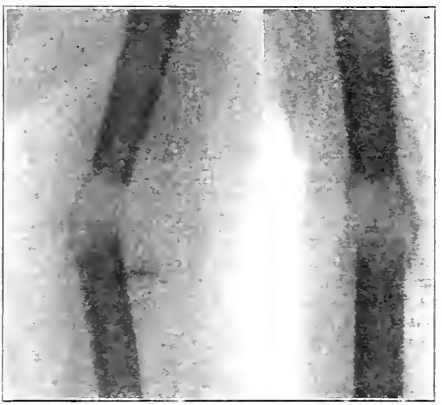

Fig. 1. Fig. 2.

Fig. 1.—Pathological fracture in the middle of shaft of right humerus; shows complete bone destruction. Fig. 2.—Fracture of humerus two weeks after first radium application; shows a callus formation at the fractured area.

The writer has shown in a previous publication [1] that in skeletal metastasis of carcinoma the two reactive processes within the bone, the osteoporosis and the osteosclerosis, are frequently present alongside, near the same tumor. Usually the osteosclerosis is very imperfect, the metastatic

nodule increases in size, suppresses the power of the organism to create new bone, and progressively destroys the old bone. The spontaneous healing power of the organism is thus quite imperfect.

The writer has demonstrated on a series of

Fig. 3.—Photograph showing the swelling of the right leg in the case pictured in Fig. 2.

cases (1, 2) that radium and roentgen therapy may enhance the healing power of the organism, destroy at least a major part of the malignant tumor, and surround it with newly formed bone. The following two cases, which have not been previously published, may further illustrate the mechanism of the action of radium on malignant tumors of the skeleton.

Case I.—Mrs. F., 54 years of age, consulted Dr. Willy Meyer, for carcinoma of the left breast. In the course of the examination there developed a pathological fracture in the middle of the shaft of the right humerus. Roentgenogram (Fig. 1) showed complete destruction of bone of the diaphysis of the humerus in an area over one inch long. There was no clear evidence of skeletal metastases elsewhere. In view of the fact that Dr. Meyer was acquainted with the writer's results in radiotherapy of skeletal metastases and the condition in the breast was operable, he decided to do a radical removal of the breast and refer the patient to the writer for the treatment of the fracture. The method of treatment consisted in covering the fractured area with three packs of tubes of radium emanation. One pack was placed over the anterior surface, the other over the external and the third over the internal surface of the humerus. In all 208.9 millicuries of radium emanation were applied for sixteen hours. The emanations were filtered with $\frac{1}{4}$ mm. of silver, 2 mm. of brass, 1 mm. of leather and about 2 inches of gauze. The splints were applied over the radium packs to retain the correct position of the bone. One week later a similar application was made for sixteen hours of 249.1 millicuries. The following week, or two weeks, after the first radium application, a roentgenogram (Fig. 2) showed a callus formation and the ends of the bone in good position. The patient could support her arm without splints.

Such a prompt formation of a functionally perfect callus in a pathological fracture which on the first roentgenogram did not show the least tendency at osteosclerosis indicates that radium therapy must be an efficient agent in many diseases of the skeleton in which osteosclerosis could neutralize the pathological process.

Case II.—Mrs. G., age 24, consulted the writer in 1920 for a tumor in the region of the upper third of the right tibia. (Fig. III shows the swelling of the right leg.) The roentgenogram (Fig. 4) shows a defect in the upper third of the tibia of an area about two inches long and one inch wide. The patient refused an amputation. The writer then excised the tumor, which invaded the muscles, and excochleated the bone to such an extent that only a thin shell of the outer wall of the compact bone of the tibia remained. A cavity was thus formed in the bone about two and one-half inches long into which was placed a specially constructed brass box containing a series of radium emanation tubes, 213.0 millicuries in all and left for 16 hours. This was followed by several applications of radium packs over the operative field. A roentgenogram (Fig. 5) taken twelve months later showed the cavity filled with compact bone. Palpation also failed to detect the cavity which was formerly present in the bone.

The analysis of these two cases, as well as of all the previous cases reported by the writer, indicates that radium causes a very rapid formation of new bone. The callus in Case 1 formed more rapidly than it would have formed in a traumatic fracture without the aid of the radium. It seems feasible to suppose *a priori* that radium therapy may also hasten callus formation in fracture and increase the success of bone implantations. In fact, Knox (3) claims to have used *x*-ray in cases in which bone grafts have been used in the restorative operations.

The analysis of Case 11, as well as of the sarcoma cases previously reported, clearly indicates that similar results may be obtained in other pathological processes of the skeleton. Multiple myeloma of the bone is more akin to lymphosarcoma than to true sarcoma, or carcinoma, and must therefore

Fig. 4. Fig. 5.

Fig. 4.—Arrow indicates a defect in the upper third of the right tibia. Fig. 5.—Arrow indicates new bone formation in the same tibia twelve months after treatment.

be more radiosensitive than the latter conditions. Chronic inflammatory diseases of the skeleton, osteitis or osteomyelitis, present frequently pathological pictures very similar to those of sarcomata of the bone. It is very difficult, for instance, to

distinguish between a giant cell sarcoma and a so-called hemorrhagic osteomyelitis. Moreover, the writer has previously (4) shown that the action of the radium and roentgen rays on tumors and on infectious granulomata is quite analogous. It is plausible to expect then that if a focus of chronic osteomyelitis were prepared surgically in the same manner as it was done by the writer in Case II, and then treated with radium, a satisfactory clinical result may be obtained.

RECTAL CANCER; OPERATIVE METHODS.

By HENRY O. SOMMER, M.D.,
WASHINGTON, D. C.

WHILE doing some literary work to find out what the late Professor Van Lennep, of Philadelphia, had done in the field of operations for rectal cancer, I found the following remarkable statement in the Transactions of the Hahnemannian Institute of Philadelphia, 1902-1903, vol. x, p. 247, at the time of the presentation of one case. "The operation of Kraske *aims* to leave an artificial anus through the sacrum *or* to preserve the sphincters and unite the divided ends of the gut." I am inclined to believe that Lennep was misquoted by some recording secretary, unless he had an entire misconception of Kraske's aims, which seems improbable, whatever the merits of those aims may be considered, as shown by the quotations later given.

His principle and *aim* was to unite the gut ends completely, in full circumference, wherever possible and advisable and to preserve the sphincters. Moreover, he did not leave an "artificial anus" through the "sacrum," but when he judged it safer to leave one temporarily, by uniting only a half circumference of the gut, he allowed it to empty through the spatium sacroischiadicum, either of natural size, or enlarged by the sacral resections if the extirpation of the tumor had required it. This has been shown by numerous other writings, as well as those quoted later for more ready reference only, but as in Lennep's own case and the case I of Kraske's quoted later this complete union is not always possible or advisable. Also, to reiterate, the resections of the sacrum are always avoided if the sacroischiadic space is large enough to obtain the objectives without.

The quotations to which I refer are in the *Medical Times*, New York, July, 1901, on page 196, sic: "The artificial anus is to be regarded merely as a makeshift which is at times very valuable as a preliminary operation" (he refers here of course to the inguinal), "but is wherever possible to be avoided as a palliative operation." Here he of course refers to both the inguinal as well as those behind after extirpating the tumor through the spatium sacroischiadicum. In his cases II and III, page 195, he showed clearly that his desire was to avoid the artificial anus. Case II: "The two ends of the gut are united in a circular suture," which means that the whole circumference is closed and not merely the half as in his case I, and in Lennep's one case referred to in the beginning. Also in his case III, page 195, "the rectum and the lower part of the S. romanum (meaning the sigmoid flexure) are pulled down from within the pelvis, resected, and united. . . . The union is very easy of execution." This was a complete anastomosis and not a half circumference. In two very creditable articles by Pennington and W. E. Darnall, I have observed the following: "Notwithstanding the unfavorable opinion respecting it entertained by many authors, Kraske's plan of sacral resections judging by the figures furnished by Bacharach gives good results (Pennington, *J. A. M. A.*, lxxi; 23, p. 1893, Dec. 7, 1819). That means of course where it is unavoidable, or the individual case requires it. I am surprised, however, that Pennington in an attempt to cover the literature or to discuss the methods so broadly has omitted all discussion of the abdominosacral, or as it would be better named, the abdomino-spatium-sacro-ischiadicum method, especially as he accentuates the abdominoperineal method and—after enunciating the principles of cancer eradication thus . . . "It is a well recognized procedure to begin the dissection from above and to work down against the lymph current" . . . —asserts flatly: "Obviously this can be done *only* by the abdominoperineal route," especially as hidden in the literature of his obscure footnote references are the following views of others whose eminence does not allow of their being so lightly discarded when so emphatically expressed. Jones says: "The combined abdominosacral operation I believe is admitted to be theoretically superior but has yet to be proven practically. . . . It may be stated, however, without exaggeration, that the proportion of 3 year cures is larger than with the posterior operation; it is quite evident that the mortality is much higher. . . . Judging by the course of my cases I am convinced that the [operative] mortality can be reduced to that of the Kraske [sacral] operation. I have operated on sixteen patients by the two-stage combined operation with three deaths, a mortality of 18 per cent. In extenuation of these figures, it may be said that no effort has been made to choose proper cases because I was trying to convince myself of its value. The 3 patients who died were all over 63 years. . . . If under such circumstances we can reduce our mortality to 18 per cent., it is fair to assume that with proper selection of cases it may be reduced to 10 per cent." Mayo says: "The *sacral* operation either as a primary operation, or as the second stage of the abdominosacral method is the *operation of choice* for the actual removal of the rectum; the great advantage of this particular operation lies in the fact that the disease can be extirpated widely at a single operation if necessary. In over 191 cases in our combined series, this type of operation was performed as a primary operation or as the second

stage of the abdominosacral method. The abdominoperineal combined method performed as a single operation is perhaps the ideal method," but he adds, "the combined abdominosacral operation in *two* stages has much to commend it and *has a mortality of less than one half* that of the abdominoperineal combined operation in one stage. This method also permits the removal of tumors of the most extensive description from the rectum proper, a situation in which the abdominoperineal combined operation affords insufficient access." But at any rate Pennington contradicts Darnall's sweeping assertion that the "old Kraske operation and others have been relegated to the junk heap." Darnall shows later on that he means bone resections in general and not the one he has named alone. Darnall's article ("Advantages of the Vaginal Route in Resection of the Rectum for Cancer," *J. A. M. A.*, June 7, 1919), has well elucidated, especially by illustrations, the applicability of the vaginal method always an elective one for some easier cases, but he has failed to discuss its limitations in full further than to admit that it "is practicable only when the tumor is movable and is situated in the lower half of the rectum," and he quite rightly says, "If it is as high as the rectosigmoid junction then the abdominovaginal method should be employed." He says "much has been written lately concerning the abdominal route, the sacral route, and the abdominoperineal routes, but I do not find that much is said about the vaginal route in women." In the *Medical Times* of August, 1901, p. 226, he will find that considerable has been written and done about the vaginal method by Rehn and others and its contraindications elucidated, especially with reference to the danger of hemorrhage, because of the "blood vessels entering the intestines from the rear," also that "always, however, will the space between the tubera ischii and symphysis be narrower than the sacroischiadic space in a normal pelvis. Others have said "in the case of the usual carcinomata affecting the parspelvica the diseased glandular structures lie directly at the external wall of the portion of the gut and farther up the sacral cavity; in advanced cases even to the promontory of the sacrum and farther up along the spinal column; from these facts we deduce that for the extirpation of the carcinomata recti these methods are the best which make the rectum accessible at the same time with the excavatic sacralis." There are other anatomical facts and points in the surgical technique of the vaginal method, which have been much discussed and sometimes practically applied, but I have referred to the literature enough except to say that it appears to us and some others that the entrance by the vaginal route depends just as much on the capacity of the pelvic entrance as that by the sacral route with perhaps one exception, *i. e.* that in a *flat rachitic pelvis the entrance may be somewhat larger.* Besides this it has been emphasized "that the entrance by the vaginal method has its absolute limits, *i. e.* posteriorly in the anal ring, anteriorly in the symphysis, laterally in the tubera ischii; whereas, with the sacral cut it is easily possible to increase the entrance by permanent or osteoplastic resections."

As Rehn and Lierman years ago practised and advocated the vaginal method for some cases, and as there have since been others who have, and as Darnall has not without some reason shown such enthusiasm for it, it is a pity that he did not support his argument by a brief citation of cases that have been so operated, their immediate operative mortality or survival and the duration of cure before recurrence.

It appears from these comments, the subject matter of basic practical work and the literature to which I have referred, and in which more ample references can be found, that it is largely a matter of specific indication as to which method shall be applied and that none of them have been "relegated to the junk heap."

Pennington has done a service by showing that a group of 218 have survived three years and a group of 130 cases 5 years or more. The figures vaguely implied under "or more" become interesting, especially as I have years ago shown groups which fall within this sphere and because such groups, being relatively small, are the ones of real interest both as to the operator's skill and the methods employed and their microscopic character. There are 2 cases of 6 years; 1 case 6¾ years; 2 cases that survived 8½ years; an unstated, but probably small, number that survived "8 and 11 years;" 1 case of 8¾ years and an ungiven, probably small number, that have survived or reached 14 and 16 years. These last two figures approach Dent's I (one) case of 21½ years, which, operated on in 1882 by an ancient method, is the longest survival of which I have seen record.

This Dent case must be regarded as a biological freak and a combination of skill and luck, and not be regarded as showing that the perineal method, no matter how good, is the best and only one to be used or there would have followed no such search for and development of later methods, as it has long been known to the masters of rectal surgery. This case was such an anomaly both pathologically and surgically, and evidently so regarded by Dent, that its main features should be explained as follows: "A large hard and somewhat nodular mass of malignant disease was found on the posterior and left aspect of the bowel just inside the anus and with the finger it was just possible to reach healthy bowel above. . . . The growth was evidently of some thickness, extending deeply into the ischiorectal fossa. . . . " On admission there were seen several small external piles, but on the posterior wall of the rectum was a hard lobulated mass about one inch in diameter. . . . The lower five inches of the bowel were removed. . . . Full control of the feces but only *partial* control of *liquid* feces was attained. The perineal operation in *this instance* appears to answer quite as well as the more modern methods of Kraske and Bardenheuer. . . . The *remarkable* feature of this case is that the patient *survived* 21½ years and then died from a disease which though it remained latent for so long a period was undoubtedly secondary to or directly connected with the mischief. He refers to enlargement and nodules of the liver and frankly regrets that there was no postmortem. There was also "*no microscopical* examination" of the tumor at the time of

the operation, which might throw some light on its true nature, and the *real* reason for such a long duration "cure."

From the *very low location* of the tumor in the rectum—"just inside the anus"—and because the finger could so easily pass through and reach healthy bowel above and because only 5 inches of the bowel were excised it is quite clear that this particular case was an elective one in which the perineal method was more or less particularly indicated, and that it was not one of those troublesome cases which because of their location, their size, and other complications are the cause of many later more radical innovations especially such as the many sacral resections and the abdominal operations and various operation combined with the abdominal.

As to the future benefits to patients it is clear, from the size and adjacent complications of the growths of tumors of the rectum and sigmoid which come to the master operating surgeons, that the general practitioner must more early suspect, scrutinize, and conscientiously interpret ill-defined anal, rectal, and abdominal symptoms and use the instrumental rectal and sigmoidal examinations especially higher up and have *x*-ray plates made rather early, even if they turn out negative, rather than too late!

Unless Pennington's interpretation of the results obtained by radium in rectal carcinoma can be disproven by more comprehensive work and publications he has virtually shown that radium is only a palliative for definitely and absolutely "inoperable cases," which is itself not a definitely standardizable term as yet, depending much upon the ability of the surgeon, and that some temporarily inoperable growths or allegedly inoperable growths were made fit for or possible of removal by operation. Hence in those patients who "absolutely refuse intervention" but are "operable" it would seem more conscientious not to yield too much to the patient's notions and spend a little effort in advising him to be operated upon, even though this may take some moral courage that may not react to the benefit of one's popular reputation in case of a fatal outcome by operation, for if the case does later progress to almost inoperability the operation and after treatment are not a comedy for either patient or surgeon, and unfortunately such are the cases that form the bulk of statistics, and are the cause of the low 3 year limit of duration "cures" before recurrence. It is also a surgical maxim that those methods of operation alone which offer a clear examination of the adjacent structures, and thorough mechanical work and eradication are the only ones which offer safe immediate results and relief of sufficiently long duration to make them worth while for the patient to undergo the risk of operation, for the average operative mortality rate is 15.6 per cent, and is still a risk that must be considered by a man with a conscience even if it does show 84.4 per cent. on the favorable side of the balance. Those methods which make this thoroughness possible, with judicious selection and prudent but courageous application, are the combined methods—and they are no novelty—the abdominospatium sacroischiadical, the abdominoperineal and the abdomniovaginal, though possibly not always in the order named. They have no sole originator and the names of their various originators and modifiers are a secondary matter, and have been amply honored, but their literary controversies, while they have helped some, have tended somewhat to obscure the issues by a mass of brilliant names whereas it is the principles they have demonstrated and expounded which are valuable, based on a thorough study of the anatomy and pathology of the pelvis and abdomen and its surgical technique. The abdomen has long been no "Forbidden City" to surgery.

ROENTGEN DIAGNOSIS OF THE PATHOLOGICAL APPENDIX.

BY CHARLES EASTMOND, A.B., M.D., F.A.C.P.

BROOKLYN, N. Y.

CONSULTING ROENTGENOLOGIST TO LONG ISLAND COLLEGE HOSPITAL, JEWISH HOSPITAL, KINGS COUNTY HOSPITAL, NORWEGIAN AND JAMAICA HOSPITALS; ATTENDING ROENTGENOLOGIST, PECK MEMORIAL HOSPITAL.

THE term pathological appendix is used in preference to chronic appendicitis because the term chronic appendicitis means that there is still an inflammatory condition existing, whereas the term pathological appendix merely means that there *has been* a pathological process which has brought about certain abnormal changes in the organ. The existing pathological condition may be quiescent and producing no symptoms either local or remote; or there may be changes of function in adjacent parts of the gastrointestinal tract without the presence of any local clinical manifestation of disease.

The roentgen examination of the appendix is dependent upon the rendering visible of the organ through the filling of its lumen with some substance which is opaque to the rays. For this either barium sulphate or bismuth subcarbonate is used. The former is now in general use because of its relative cheapness and is in every way satisfactory. Fluoroscopic examination is of even greater value than the radiographic method in the study of the appendix. About ninety per cent. of all appendices may be rendered visible. This statement is based on the consensus of opinion of a majority of roentgenologists. The mere filling of an appendix by the barium or bismuth meal does not, in the author's opinion, signify pathology.

It may be worth while to describe the technique for an examination for the detection of pathological conditions referable to the appendix and the procedures to be carried out. The patient is given a meal of two to four ounces of barium in one pint of buttermilk or fermented milk six hours before the first observations are made. This meal may be taken at home or may be given at the laboratory.

At the examination at the six-hour period the following points are to be considered:

1. Stomach residue; if present, its quantity.
2. The relative ileal residue.
3. The terminal ileum. Is it fixed or freely movable? Is its lumen regular or irregular? Is it straight or is it kinked?
4. The appendix. Is it visible? If it is visible, is the lumen regular or irregular? Is it freely movable, or is it fixed as a whole or at any point? Is it straight or is it kinked? Is it tender?

5. Cecum. Is it dilated? Are its margins regular or irregular? Is it fixed or is it freely movable? Are there points of local tenderness?

6. Head of barium column. To what point has the barium progressed during the interval?

Twenty-four hour period.—That is to say, twenty-four hours after the ingestion of the barium meal; the same points are covered as are they at the forty-eight hour period. If the cecum is not well emptied at this time, the patient continues to return at twenty-four hour intervals, notes being taken in reference to all the above points until the cecum is empty or practically so. The question of barium retention in the appendix after the cecum is empty is of the greatest importance.

Head of the barium column.—The progress which the barium meal makes during a given interval is an excellent determining factor of the power of function of the parts concerned. Under normal conditions the head of the barium column at the six hour period is in the proximal portion of the transverse colon and at the rectum at the twenty-four hour period.

Before considering pathological conditions, it is necessary to describe the normal tract. The stomach should be empty at the six hour period. Residue at this time means interference with motility. This may be due to mere atony as is seen so frequently in ptosis; it may be caused by local gastric, pyloric or duodenal pathology, or it may be the result of a reflex (pylorospasm) from disease of the gallbladder or appendix.

It is difficult, in fact almost impossible, to state the amount of ileal residue which may be present at the six hour period without its being considered pathological. Should the ileum be completely emptied, one anticipates local pathology. Excessive residue depends upon many factors and of itself is of little importance. If the stomach is still discharging its contents into the small intestine at the six hour period, it is but natural that the ileal residue would be greater than if the stomach emptied rapidly. On the other hand there may be an obstructive condition in the cecum or the right side of the intestine which may cause a damming back of the intestinal stream. The terminal ileum normally presents a uniform diameter. The terminal four or five inches are freely movable because of the long mesentery. Fixed kinks and angulations are not present under normal conditions.

The normal appendix presents a homogeneous lumen of uniform diameter; it is freely movable, is not tender upon pressure, and presents no sharp kinks or angulations and with the cecum it is empty.

The cecum normally presents a range of mobility of from one to two inches; its margins are smooth and regular except for the possible appearance of a peristaltic contracture; it is not tender.

The diagnosis of pathological appendix depends upon the presence of either direct evidence in the form of abnormalities of the appendix itself or upon secondary evidence through the existence of changes in the adjacent parts, the result of appendiceal inflammation.

The direct evidence through local changes in the appendix is as follows: 1. *Lack of homogeneity of the appendiceal lumen.* This means that there are one or more areas within the lumen of the appendix which do not present the same density as the remaining parts because of a diminished amount of barium present. A local area which fails to show the full amount of barium, in other words a filling defect or local area of diminished density, is usually indicative of the presence of a concretion. Appendiceal concretions frequently possess sufficient density to be apparent on the *x*-ray plates and thus establish the diagnosis without the use of the barium meal.

2. *Irregularities of lumen.*—This is usually seen to be of two types. There may be dilatation of the tip producing the socalled "clubbed appendix," while the other type of lumen variation is a contraction of the lumen over a larger or smaller part of the organ, the result of chronic inflammatory changes.

3. *Abnormal Fixation.*—The normal appendix is freely movable. Abnormal fixation may involve any portion of the organ from its tip to its base or the entire organ may be bound down.

4. *Tenderness* of the appendix upon palpation is also indicative of pathology. By tenderness is not meant that upon pressure of the palpating finger the patient says that it hurts, but rather that one is able to feel the unconscious response in the way of a tightening of the abdominal wall.

5. *Abnormality of form* through angulation or coiling of the organ so that it appears like a spiral spring does not indicate pathology, but with the existence of such an appendix there are usually additional factors present and drainage is poor.

6. *Retention of the contents* beyond the emptying of the cecum. This is very important.

The indirect evidence is of value in confirming the evidence shown by the appendix itself and in those cases where the appendix cannot be visualized, it is of extreme importance. This indirect evidence is based on:

1. *Adhesions of the terminal ileum.* These are identified by the immobility of the part, its failure to hold its barium contents, by which is understood that the barium is seen both proximal and distal to the affected part with none between. The previous incidence of typhoid fever must be excluded as a source of these ileal adhesions.

2. *Abnormal fixation* of the cecum is very suggestive, if not absolutely indicative of old appendiceal inflammation, provided that malignancy and tuberculosis, especially the latter, can be excluded. A sign of importance and one to which attention has only recently been called is a flattening of the inner margin of the cecum. This is very suggestive of appendiceal disease of the chronic type, but it must always be borne in mind that this appearance may be the result of contraction following an appendiceal operation. In the presence of this sign, inquiry must be made as to whether the appendix has been removed.

3. *Functional disturbances.*—There may be very rapid advance of the barium through the colon so that at the six hour period the head of the barium column may be even at the rectum. This constitutes the socalled "racing colon." It is of interest in such cases to find that the barium may be distributed throughout the colon at the six hour period, but that practically no additional progress has been

made in the subsequent eighteen or more hours. Retention of barium in the cecum after emptying of the colon beyond signifies adhesions.

Another functional disturbance that must be mentioned is pylorospasm. This may occur associated with disease of the gallbladder but is more often associated with appendiceal conditions. This is of importance from the clinical standpoint because, not infrequently, the patient complains merely of epigastric disturbances with a local point of tenderness in the epigastrium (solar plexus) with absolutely no signs or symptoms referable to the right iliac fossa. This is also of interest in this connection because frequently pressure upon the appendix will reproduce the umbilical or epigastric pain of which the patient complains.

Before leaving the subject, attention should be called to associated lesions in this field which might give rise to symptoms simulating those of pathological appendix. The Lane kink is familiar to all and needs no special mention. Adhesions of the ascending colon or around the hepatic flexure in the form of bands are also familiar conditions. New growths of the cecum are not uncommon and tuberculosis is occasionally encountered. Insufficiency of the ileocecal valve with or without tenderness on pressure upon the valve is often found. Spasm of the ileocecal valve is occasionally encountered in patients who clinically present symptoms of chronic appendicitis. Little has been said of this condition but it is a distinct entity and the roentgenographic findings are very definite.

In conclusion the roentgen examination of the appendix is exact in its findings and it is not too much to state that the patient suspected of having chronic appendicitis should have the benefit of a competent and complete *x*-ray examination before operation. First, to learn whether the disease does lie in the appendix and, second, to determine whether there is an associated pathology elsewhere in the neighborhood. Furthermore, with previous knowledge of the location of the appendix and of existing complications the operative procedures may be shortened and at the same time associated complications may receive proper treatment.

TREATMENT OF FOOTBALL INJURIES.

By HARRY EATON STEWART, M.D.,

NEW HAVEN, CONN.

ATTENDING SPECIALIST IN PHYSIOTHERAPY, U. S PUBLIC HEALTH SERVICE.

Last year a preliminary report was made of the results obtained by the use of physical methods in the treatment of injuries to athletes.* The experience derived this year from a still larger number and greater variety of cases, coupled with the use of additional types of apparatus, has modified to some extent the estimate of the relative value of certain treatments. It has more than confirmed the opinion that the period of disability from these injuries can be materially shortened by the proper blending of various physiotherapeutic measures. Since football is responsible for such a large part of the injuries due to athletic competition, the more common types of trauma met in that game only will be considered in this paper.

Many a football championship has been won in the medical consultation room by the proper selection of treatment in the case of some invaluable player. The problem confronting the coach and trainer is no easy one. Injured players must be kept in touch with the development of the team and participate in kicking, passing, signal drill, and scrimmage at the earliest possible moment. It is not enough that they be ready to play in the final game, but they must be returned in time to regain both condition and speed. Most of the severe injuries occur in the more strenuous mid-season games, so that the time within which they must be gotten into condition again is a comparatively short one.

It would seem that some plan could be arranged by the physician, physical director, trainer, and coach similar to the convalescent conditioning exercises used in many of the army hospitals. There men softened by months of hospitalization were gotten into condition in spite of the handicap of a fracture or ankylosed joint. It should be a simple matter to work out exercises that would *keep* a player in good condition for a few days or weeks.

The Yale players were referred by Dr. Leonard Sanford, Mr. T. A. D. Jones, and Mr. John Mack. The Princeton men were sent by Dr. D. B. Sinclair, Mr. William Roper, and Mr. Keen Fitzpatrick. The report of the excellent work of Lieut. M. Hines Roberts, M.C., U.S.N., with the football injuries of the U. S. Naval Academy team is quoted through the courtesy of the Commandant, Rear Admiral Scales.

In his work with the Annapolis team during the season of 1920 Dr. Roberts treated over three hundred men from the "A" and "B" squads and class teams. Muscle contusions were the largest class of cases, followed by sprains, fractures, dislocations, strains, and synovitis.

These cases were treated by prolonged radiant light and heat, high frequency in the form of direct diathermy twice daily for one hour, followed the next day by the sinusoidal current. A small portable machine was used. The players were allowed a light work out, signal drill, etc., as a rule on the second day, with scrimmage the third. Great care was taken to protect against reinjury. All injuries were reported at once to physician or trainer and the team "rubber" was never allowed to work on injuries except under direction.

Among the joint injuries those of the knee were most common and most severe. Rest, baking, diathermy, and support were used. Muslin bandages proved better than elastic supports for the knee. Canvas figure-of-eight bandages of the ankle worn by the entire squad prevented many injuries to this joint. When injured, prolonged rest, vigorous treatment, and additional adhesive support carried well up the leg were used. There were seven fractures during the season. Rest in bed was insisted on in tenosynovitis of the Achilles tendon.

Case I.—B. H. A. Annapolis.

Injury.—Received blow to medial surface of left thigh above knee. Considerable swelling, pain, and stiffness over rectus femoris and adductors.

Diagnosis.—Contusion of muscle.

Treatment.—Hot packs followed by direct diathermy (one hour) three hours after injury. Excused from formations. Second day, diathermy and sinusoidal current with improvement noted. Light workout. Third

*Stewart: The treatment of Injuries to Athletes, *Journal A. M. A.*, April 3, 1920, lxxiv, pp. 947 and 948.

day, much better. Treatment continued, padded and s rimmaged. Fourth day. No disability remaining Dismissed.

CASE II.—W. C. C., Annapolis.

Injury—Repetition two days later of severe blow to rig h. thigh. Was swollen, hard, k otty, and tender.

Diagnosis.—Severe muscle contusion.

Treatment.—Rest, baking, and diathermy. Next day sinusoidal current added. Light work out the third and scrimmage the fourth day. Fifth day reinjured worse than before. Treatment repeated daily and dismissed on the eleventh day.

CASE III.—D. B. L., Princeton.

Injury.—Right shoulder twisted and kicked in Annapolis game two weeks ago. Patient able to raise arm to throwing position but unable to execute the movement because of pain and weakness. Marked tenderness over coraco-acromial ligament.

Diagnosis.—Sprain of shoulder.

Treatment.—Radiant light and heat 20 minutes followed by direct diathermy 2000 m. a. 20 minutes, and vibration Patient able to go through vigorous throwing movements. Two days later threw a number of passes in the Harvard game with some pain after the first throw. Treatment repeated twice the following day. Had no further disability.

CASE IV.—T. M., Yale.

Injury.—After a hard fall noticed pain and weakness on inner side of left thigh just above knee. Insertion of the vastus internus was swollen and tender.

Diagnosis.—Tear of insertion of vastus internus.

Treatment.—Support, radiant light and heat, and diathermy. On third day light massage and vibration added. Continued scrimmage with one slight reinjury. Discharged on the fifth day.

CASE V.—R. C. G., Princeton.

Injury—Kicked on right calf six weeks ago with same injury one week later. Muscle sore and stiff, unable to rise on the toes.

Diagnosis.—Traumatic myositis.

Treatment. Radiant light and heat with 1500 c.p. lamp, whirlpool bath, and diathermy. No disability after third day.

CASE VI.—R. E. J., Yale.

Injury.—Hit on right thigh by shoulder of tackler two weeks ago. Received "rubbing" at first followed by daily baking and poulticing with no improvement. Examination showed a large dense mass covering about half the front of the thigh.

Diagnosis —Chronic traumatic myositis.

Treatment.—Radiant light and heat, di ect diathermy 2200 m.a. for 20 minutes followed by hacking massage and heavy vibration, Static Morton wave after third day. Ran three miles on fourth day and returned to play on the sixth.

Comment.—I have given Dr. Roberts' results because they show what a physician with an inexpensive equipment can accomplish by the careful application of physiotherapy to injuries. It will be noted that the type of portable high frequency machine used by him delivers not over 1000 milliamperes of current, which necessitated the longer treatment given. The current from this type of machine used to produce muscular contraction is perhaps more of a wave than a true sinusoidal current, but accomplishes the desired result

Dr. Roberts' technique of applying diathermy on the first day gave results which indicate that at least one day of disability may be saved by this method. The fear of reestablishing capillary bleeding in a torn or bruised muscle by the active hyperemia induced by diathermy has heretofore led to a twenty-four hour delay in the application of this current. The problem resolves itself into some method of applying heat to increase active hyperemia followed by the removal of the excess blood and lymph through mechanically squeezing the muscle.

The first requirement is perhaps best met by a combination of radiant light and heat, steam towel or oven, and direct diathermy. Indirect diathermy (with the autocondensation cushion attached to one pole and a movable electrode to the other) or simple high frequency from the Tesla pole may be used. Direct diathermy with sheet metal electrodes seems to give the best results. They may be placed on opposite sides of the part, or above and below a joint such as the elbow. When used in the latter manner they should entirely encircle the limb. A heavy lather of soap will keep perfect contact with the skin and prevent burns. Rubber bandages are more satisfactory than any other type.

The first requirement is perhaps best met by a etc., in fresh injuries, massage, sinusoidal current, and Morton wave from the static machine are to be preferred. When the exudate is more or less organized static sparks and heavy vibration are indicated.

It is of the greatest importance that the future welfare of the player be constantly kept in mind and that treatment be kept up beyond the season if necessary, so that he may not be handicapped with chronic weakness. This unfortunate condition arises all too often when the season is over and a man is no longer of value to the team.

420 TEMPLE STREET.

INDICAN AND A HIGH SPECIFIC GRAVITY OF THE URINE.

BY JOHN C. WARBRICK, M.D.,

CHICAGO.

THE question might be asked: Is there any relation between the amount of indican in the urine and a high specific gravity of it?

A much higher specific gravity than usual might tend to point to that dreaded disease diabetes, or to some metabolic disturbance in the body, due as it might be, to some excessive nervous tension for a time. The presence of more or less indican in the urine may have some relation to the amount of putrefaction going on in the bowels; however, a high specific gravity can occur where the amount of indican is small, as has been proved more than once.

A high specific gravity can also occur, as has been found where the amount of chlorides, phosphates, and sulphates is quite small. It cannot then be said that the amount of indican regulates the specific gravity of the urine, for a high specific gravity may be found when the amount of indican is high and also when it is low.

The amount of indican no doubt has a relation to the degree of putrefaction going on in the intestines, which of course bears a relation to the amount of protein food ingested from time to time. The degree of putrefaction going on in the intestines would seem to depend a great deal upon how the proper hygiene of the body is carried out. If it is well maintained the amount of indican can hardly be very high, because it is got rid of by the system when well regulated in any quantity. If, however, this is neglected, as it often is, the amount of indican may gradually become high.

An examination of six specimens of urine was made in each instance where the specific gravity was unusually high. The case was that of a man just a little beyond middle life, in full possession of both mental and physical vigor, but at times subjected a nervous tension from overwork.

In each specimen of urine examined the specific gravity was found to be very high, so that the tendency was to think it almost a sure case of diabetes. This, however, was soon disproved, because at no time could any sugar be detected in the urine after a careful examination. Thus the condition of the urine was in no way related to any seeming diabetic state.

The specific gravity of the urine ranged from that of the high figure of 1036 to a much higher one still of 1046—rather an unusual one to find except in severe cases of diabetes.

The amount of chlorides, phosphates, and sulphates was noted at each examination and the degree of indican was also registered. The figure for the chlorides in each instance in this case was not high. In one case only did it extend well beyond the maximum daily amount, but it was over the minimum daily figure in all but two cases, when it registered the same. In only one case where the point for the chlorides registered high was the index for the amount of indican also found to be high. Indican, however, was present in two cases only where the specific gravity of the urine was found to be high, so that in four of the cases no indican could be noted.

The amount of sulphates in these cases was fairly high, tending to point to suboxidation of tissue change. In four cases it equalled the daily maximum figure and in two of them it was far beyond that point; however, no indication could be found at either of these examinations.

As for the amount of phosphates in one case only was the amount high, and this registered beyond the maximum daily figure.

The examination of each specimen of urine was made soon after a full meal had been taken, which was generally after breakfast in the morning. The results of the urinary examinations are as follows, and it may be said for those who do not readily understand the figures for the amount of chlorides, phosphates, and sulphates, that the urine was of course sedimented in a graduated tube for the specific purpose and these are marked off all the way from 1 c.c. to 15 c.c., such tubes not being at all new.

The figures for the chlorides, phosphates, and sulphates represent the amount of each in c.c. precipitated in the tube after the solution necessary in each instance has been added to the urine; for instance, the amount of chlorides found might be any way from 5 c.c. to 50 c.c. The opposite figure is the amount of c.cs. found changed into grains, as, for instance, if the amount of chlorides was 15 c.c., then this multiplied by 15.5 grains in one gram gives the amount of grains, 232.5 of the chlorides, which is not very hard to understand.

Always multiply the amount of chlorides, phosphates, and sulphates found each time in c.c. by 15.5, and you get the amount of grains a day of each passed. The benefit of this is evident, for it is important to know the amount of tissue change going on in the body, whether there is suboxidation or superoxidation of the tissues, and the amount of chlorides found, also that of the sulphates, tends to indicate the degree of this.

The figures also act as an index of the amount of food taken into the body.

Medicolegal Notes.

Physical Examinations in Personal Injury Cases.—The Missouri Supreme Court states its views as to the trial court's power to appoint medical examiners in personal injury cases thus: "The law invests the trial court with authority to appoint physicians to make physical examination of the plaintiff in a physical injury suit. The defendant cannot demand it as a matter of right, but the court in its discretion may do it in the furtherance of justice. When the court makes such an appointment, he does so because he determines in his discretion that the case calls for the opinion of disinterested and unbiased physicians, not friends of either parties, whose testimony is likely to be biased. This court, in case of State ex rel. v. Anderson, 194 S. W. 268, placed the authority of the court in such cases upon the same ground as the general power to compel a discovery. Wigmore on Evidence, vol. 3, § 2194, treats of the subject in the same manner and says: 'Apart from specific privileges, then, a person is bound, if required, to furnish evidence by exhibiting his corporal features, his chattels, and his premises to the inspection of the tribunal or its duly delegated officers.' Wigmore then quotes from a Federal case of Justice Brewer as follows: 'A person who testifies to his physical condition may be compelled (there being no improper exposure of person) to uncover his body, that the jury may see whether there be such a physical condition as he has testified to.' The power to make such an appointment involves an order requiring the plaintiff to submit to examination. The court could not compel plaintiff to submit to such examination by the witnesses for the other side. The physicians appointed in such cases are the officers of the court. The order is made because an exhibition to the jury or the court of the infirmities about which the inquiry is made would not disclose the facts as fully and clearly as the examination of experts would reveal them."—Atkinson v. United Rys. Co., Missouri Supreme Court, 228 S. W. 483.

Explanations by Experts of X-Ray Photographs.—In an action for injuries to the plaintiff's leg by a fall on a defective sidewalk, it was held that it was not error to refuse to permit the defendant's expert to testify as to what appeared in the *x*-ray photographs of the injured leg, in view of the court's previous holdings that the photographs themselves are the best evidence of what appears on them. The court said: "It is proper for an expert to explain an *x*-ray photograph in such particulars that are not understood by a layman. See State v. Matheson, 142 Iowa, 414, 120 N. W. 1036, 134 Ann. St. Rep. 426. What the jury could see and understand about the matter is not the subject of expert testimony, and this we understand to be the effect of our prior decisions. A radiograph may be used for purposes of demonstration by an expert as though he had the object itself before the jury for explanation. Sheldon v. Wright, 80 Vt. 298, 67 Atl. 807. That the bone can be distinguished from the flesh in an *x*-ray photograph, and that the bone would make a heavier shade than the muscle is proper expert testimony. Such scientific facts would not be known by the average layman. Missouri, K. & T. Ry. Co. v. Coker (Tex. Civ. App.), 143 S. W. 218."—Daniels v. Iowa City, Iowa Supreme Court, 183 N. W. 415.

FIGHTING TUBERCULOSIS WITH CHRISTMAS SEALS.

THE sale of Christmas seals as a feature in the war against tuberculosis has come to be an established annual event, which serves the double purpose of raising funds for the work and of focussing the attention of the public on the need of keeping up a continuous fight against the white plague if we are to hold the ground that has been won. That the fight is well worth while is shown by the fact that the death rate from tuberculosis has been steadily declining since an organized effort to control the disease has been in operation. The death rate from tuberculosis in all forms in the Registration Area of the United States in 1900 was 201.2 per 100,000 inhabitants; in 1904, the year the National Tuberculosis Association was founded, the death rate was 202.6. Since this time the number of deaths from tuberculosis has fallen steadily from year to year, which the exception of the years 1917 and 1918, when it increased, until in 1919 it was 125.6 per 100,000 population.

It is estimated that there are approximately 132,000 deaths a year from tuberculosis in the United States. In 1919 in the Registration Area there were actually reported 106,985 deaths from tuberculosis. The Registration Area then included 81 per cent. of the population of the United States. At the same rate there would be 132,000 deaths in the entire country. If the prevalence of tuberculosis had not diminished since 1900, we would have lost more than 210,000 lives in 1920. Because of this decrease, therefore, in one year alone more than 75,000 lives have been saved.

In the attainment of these results the sale of Christmas seals has been by no means an insignificant factor. The way in which this movement became one of national scope is interesting. The first tuberculosis Christmas seals to be sold in this country were offered to the public in Wilmington, Delaware, through the efforts of Miss Emily P. Bissell in 1907. She had read of the use made of seals to raise funds for a children's hospital in Norway, and she believed that a similar fund-raising method could be followed successfully here. From the proceeds of the first Christmas seal sale $1,000 was donated to help start Hope Farm in Delaware. Miss Bissell was secretary of the local Red Cross, and in 1908 she was backed by the national Red Cross in a country-wide seal sale.

In 1919 the National Tuberculosis Association began to conduct the Christmas seal sale annually in its own name. The amount secured through these sales has grown from $135,000 in 1908 to $4,000,000 in 1920. The total amount raised in the preceding thirteen sales was approximately $16,000,000. This year there will be put on sale 920,000,000 stamps. The funds raised from seal sales have been called "seed money" and have been wisely used to spread information regarding tuberculosis and to organize public opinion in an effort to control and prevent the disease. During the period in which this work has been carried on, sanatoria and other institutions to treat tuberculosis, worth in the aggregate over $150,000,000, have been built. The National Association has always directed the expenditure of these funds for the specific purposes represented by that organization. The conditions of poor housing, overcrowding, and unemployment that we are experiencing as an aftermath of the war call for unusual effort both in educational work and in actual financial relief if progress in the reduction of the tuberculosis death rate is to continue on the same scale as during the past fifteen years.

THE PSEUDOPARALYSIS OF RICKETS.

THE pathogenesis of pseudoparalysis of rickets is still very obscure because of insufficient histological data, so that it is only by hypotheses that the mechanism of this affection can be surmised. Berg, who seems to have been the first to have emitted an opinion on the subject, states that when a lower limb is set in motion by muscular contraction and a step is taken the sum of the work accomplished is composed of the two following elements: firstly, a reaction against the limb to be moved, and secondly, the communication to this limb of the force necessary to move it. The sum of these two actions represents the muscular work accomplished; therefore, it is evident, according to this observer, that when one is standing motionless all the work employed is to maintain rigidity of the lower limbs and to overcome the tendency to fall. Now when walking, the work accomplished is increased, the body being at the same time transported and supported. The muscular tissue, being weakened by the defective nutrition of the rachitic blood, is incapable of performing these two acts simultaneously, and in certain cases in which the force is still sufficient to carry the body weight, it will nevertheless be insufficient to originate movement. This incapacity is still more increased by the weakness of the ligaments and osseous system and by the flaccidity of the muscles. On the other hand, the extreme sensitiveness of the muscular tissue is likewise a cause, and when pain is present it is clear that the little patient will seek a restful attitude.

Unquestionably, these propositions emitted by Berg are quite acceptable, but it appears only logical to give a larger place to pain than does this observer. In reality, what are the clinical data found in these cases? Usually they are as follows: For some time past the child has become tired much more quickly than was his wont, his movements are less precise, he staggers when walking, standing is difficult and possible only for a short time. Finally, even when making slight movements, the child cries out and by his gestures shows that he suffers. This pain has certainly great importance, and it is to prevent its occurrence that the patient immobilizes his joints and avoids all motion. To remain still so as not to suffer is the fixed idea of the patient.

To explain the cause of the pain engendered in rachitic pseudoparalysis one is compelled to enter the domain of hypotheses. In these cases there is no detachment of the epiphyses as in Parrot's syphilitic pseudoparalysis, neither is there any juxta-articular traumatism as in Chassaignac's disease. Radiography of these cases shows that there is not a trace of solution of continuity or detachment of the epiphyses, neither is there any skeletal tumefaction as in Barlow's disease. Rachitism is the only cause. It is undoubtedly by an excess of perturbation that this morbid process causes in the skeleton in the proximity of the epiphysary points, from defective nutrition as well as, perhaps, by muscular and tendinous changes, that the clinical phenomena encountered in these cases of pseudoparalysis should be explained. The lack of solidity of the limbs in the proximity of the joints, the abnormal softness of the insertions of the tendons, the defective nutrition of the groups of muscles are all so many important factors which disturb the accomplishment of the motor functions and are susceptible of giving rise to pain, and hence the appearance of pseudoparalytic phenomena.

THE RIGHTS OF CHARITY PATIENTS.

One of the problems that is always confronting visiting and resident physicians in hospitals having large open wards is that of the unruly or obstinate patient. It is naturally quite annoying to the busy physician who is giving his time and skill gratuitously to be met with a refusal to submit to very necessary diagnostic procedures or to treatment of an indispensable sort. In such cases the physician, who is accustomed perhaps to have his word regarded as law by the hospital staff, is too likely to issue a curt order that so-and-so be done, regardless of the patient's wishes.

One must pause a moment, however, to consider several angles to this question. The patient himself, even though poor and ignorant, and for the time being receiving free treatment, has certain rights. Let the physician endeavor for a moment to get the patient's viewpoint. Let him suppose himself a layman obliged to seek treatment in an open ward. Suppose he is told that he must submit to a metal instrument being thrust into his bladder, or a large needle into his spinal column, or that he must take castor oil, which he detests, or be thrust out into the world again. Diagnostic and therapeutic procedures, we must remember, which have become commonplaces to us, seem often mysterious and terrible to patients. Too often, moreover, instead of taking a few minutes to explain their innocuous nature, the doctor simply orders them done and the patient, when the interne or nurse appears with formidable looking instruments, is frightened and easily becomes antagonistic. Lumbar puncture, for example, which, except in very exceptional circumstances, is absolutely free from danger and no more painful than a hypodermic, seems an alarming operation to a layman. Too brusque attempts to explain it are worse than useless, for the mere idea of someone thrusting a needle into the spinal column gives the patient visions of sudden death or at the least of excruciating pain.

Let the physician then bear in mind, first, that the charity patient is possessed of inalienable rights including those of free choice as to whether or not he will take certain medicines or submit to physical examinations. The fact that these rights are frequently ignored and that these patients, being usually poor and without influence, seldom seek legal redress, has no bearing on the moral aspect involved. Thus, secondly, the physician should read diligently the history of medicine until he becomes convinced, which he will in time, that no diagnostic manipulation or therapeutic procedure can be certainly said by the physicians of the age which employs it to be so indispensable and of such absolute value as to warrant them in seizing another human being by the throat, so to speak, and forcing him to submit to it.

Steinach's Rejuvenated Rats.

In a book entitled "Die Verjüngung," by Steinach, which appeared last year, there were several case histories of elderly men who had been "rejuvenated" by a very simple operative procedure, consisting in the subcutaneous division of the vas deferens, which is stated to confer all the benefits of testicular grafting. However, the author emphasized especially the alleged results of some elaborate experiments on rats which led the way to the human trials. The book made some talk and was more or less severely criticized, but the most severe criticism has recently been voiced by Fiebiger, who noted in the rat-photographs of the book that the animals suffered from mange, and declares that the entire experimentation is vitiated because in investigations of that character the animals should necessarily be in sound health (*Wiener klinische Wochenschrift*, July 28, 1921, xxxiv, 30). Rat mange, or rat-scabies, is extremely common and due to a parasite closely related to the *Sarcoptes scabiei* in man. The lesions due to the mite comprise pustules, crusts, and shedding of hair. The irritation causes also the formation of condylomata acuminata. The areas of preference are the ears and tail, and in mild cases no other regions are implicated. In more severe cases the nose and ano-

genital region suffer. Finally the entire trunk, paws, etc., may be involved. As an occasional complication may be mentioned the presence of rat lice. Rat-mange is by no means a local affection, for in the more severe cases it leads to anemia, emaciation, and cachexia. While the rats in Steinach's experiments must necessarily be senile it is manifestly improper to make use of animals with advanced mange; and the photographs show clearly that they were thus affected. Steinach, however, ignores the affection in his book. The crux of the matter is that mange when severe will induce precocious senility, and when the condition is cured the rat may recover his original status, which may involve return of potency. Steinach was aware that the animals were in part lousy, but claims that after delousing their condition was not essentially altered for the better. Fiebiger does not, of course, assert positively that Steinach's work is a total failure, but evidently it must be controlled by other experiments in which the senile condition is surely primary and not precociously due to severe mange. He also points out that the ages of Steinach's rats were too low for true senility (19 to 38 months).

Spirochetes in the Blood in Erythema Multiforme.

Apparently erythema multiforme has been added to the increasing list of the spirochetoses, although clinically there seems to be little similarity between it and the other members of the family. The discoverer of the organism in the blood is Professor Massini of Basle (*Schweizerische medizinische Wochenshrift*, August 11, 1921, li, 32). The spirochete in question bears a notable resemblance to that of Weil's disease or spirochetosis icterohemorrhagica. By reason of the lively motions exhibited, the author chooses to call the new organism *Spirochæta agilis*. It cannot be seen in recent blood, but on the fourth day of a blood bouillon culture can readily be seen in the dark field. In the light field no stain yet tested can bring the organisms into view. They have been cultivated only as far as the second generation. In the body they do not appear to enter the blood before the fifth day of the disease and disappear about the ninth. The patient in whom the organisms were found was a woman aged 61 with an alleged rheumatic history and a further record of sciatica and bronchitis. During 1921 she had repeatedly suffered from swollen ankles and finger joints. When admitted there was bronchitis but rheumatism was quiescent. The disease for which she sought treatment was a febrile angina (diphtheria excluded), in the midst of which appeared the outbreak of erythema multiforme. The latter was typical and need not be described. Whether the spirochete entered the blood from the fauces is unknown; there seems to have been no attempt to cultivate it from throat smears.

Propagation of Gastric Toxins and Ferments Along the Vagus Nerve to the Medulla.

The earlier reports of the original work along this line of Loeper, Debray and Forestier were of experiments with the abnormal ligated stomachs of animals. When certain substances were introduced into such stomachs they could be shown to diffuse the length of the vagus, in a manner somewhat similar perhaps to that shown by tetanus toxin under other circumstances. The vagus was practically always impregnated with some of the contents of the stomach, including pepsin. The later results are reported in *Le Progrès Médical* for August 6, 1921, xlix, 32. In the first experiment with two fasting dogs erosions were produced in the gastric mucosa, using a sound or similar implement. The pylorus was now tied and a solution of formal in glycerin injected into the stomach. Two hours later the vagus, medulla, and sciatic nerve were tested, and while the first named gave a positive reaction, the medulla gave a doubtful one, and the sciatic control was flatly negative. The experiment was repeated with tetanus toxin, and guinea pigs were tested with pulp made from the several nerve structures. Both the vagus and medulla gave positive reaction, but the sciatic a negative one. Injection of antitoxin prevented the positive results. The third experiment was made with pepsin. It has long been known that this substance diffuses along the vagus during digestion. An extract made from the vagus and one from the bulb both showed peptic powers on albumin.

News of the Week.

Plague Kills Many in India—A despatch from London reports that hundreds of persons are dying of plague in the city of Jubbulpur, the capital of a district in central India. It is said that deaths are so numerous that it is impossible to bury or burn the bodies of the dead, and that the city is almost panic stricken.

United States Government Buys Hospital in New York.—The Government has purchased the Roman Catholic Orphan Asylum at Kingsbridge Road and Sedgwick Avenue, the Bronx, and expects to replace the home with one of the largest hospitals in the country for the care of disabled soldiers under the jurisdiction of the United States Public Health Service. This will make it possible to return the Polyclinic Hospital to its trustees by the first of the year. The new hospital will not only care for the 300 patients now in the Polyclinic Hospital, but for the 1000 in the Fox Hills Hospital on Staten Island. It is believed that this move will go a long way toward solving the problem of hospital facilities for ex-service men in this district.

Prussian Marriage and Birth Rates.—Prussian statistics show that the marriage rate has doubled since 1913. About 15 persons in every thousand were married in 1913; in 1920 the rate was 28 and now it is 32. The annual birth rate has not kept pace with the increase in marriages. In 1920 the average birth rate per thousand was 25, while in 1913 it was 29. The tendency of the birth rate to decrease was already in evidence a decade before the war. The surplus of births over deaths was 10 per thousand in 1920 and 13 in 1913.

Drugless Physicians Push Legislation.—The Drugless Physicians' Association is sponsoring two bills which will be proposed at a special session of the Oregon Legislature to be held soon. One of these bills would limit the charge for an

operation by any doctor to $50, and the other would require all prescriptions to be written in English. An unsuccessful effort was made at the last legislative session to pass a bill providing that all prescriptions be written in English and made in triplicate with an exact diagnosis of the ailment and with a statement as to the particular use of each drug prescribed.

Increase in Drug Addiction Reported in New York.—A great increase in drug addiction in New York City is reported by Dr. Carleton Simon, special deputy police commissioner, for the quarter ending September 30. The arrests from January 1 to October 1 numbered 2488, while those for the third quarter alone numbered 932. Of 659 cases brought to trial 93 per cent. of convictions have been obtained. According to this report over 50 per cent. of those arrested have criminal records. The increase in the number of arrests for addiction is coincident with the enactment of the new amendment to the Sanitary Code relating to habit-forming drugs which went into effect a little over two months ago.

Auto Accidents in New York State.—According to the report of the National Highways Protective Association, 213 persons met death by automobiles in the State of New York, including New York City, during the month of September. In New York City during the past month 47 persons were killed by automobiles, 10 by trolleys, and 3 by wagons.

Conference on Hospital Coordination.—Plans for the creation of a permanent board to coordinate hospital work among the health services of the Government were discussed by President Harding on October 8 with a committee representing about a dozen governmental agencies which deal with hospitalization and similar functions. Reports submitted showed that more than 7,000 beds are now available in Government hospitals. Among those present at the conference were Brigadier-General C. E. Sawyer, Surgeon-General Ireland, Rear Admiral Stitt, Director Forbes of the Veterans' Bureau, and Dr. Lavender of the Public Health Service.

Experts to Study Longevity.—Statisticians of the Census Bureau are preparing a special report based on a study of 3,500 men and women in the United States who have reached the age of 100 years or over. All available data surrounding the lives of centenarians will be collected. It is hoped through this investigation to gain new light on the question as to how to live to an advanced age, on the question of whether men or women live longer, and as to the effect of marriage and celibacy on longevity.

Hospitals Consolidate.—The Laura Franklin Free Hospital for Children, at 17 East 111th Street, will become a part of the new Fifth Avenue Hospital of New York on January 1, 1922. The Laura Franklin Hospital will not lose its identity but will be concentrated on one floor of the new Fifth Avenue Hospital, where there will be accommodations for more than again as many children as it now cares for.

Hospital Addition Opened.—A new building providing fifty additional beds at the Lutheran Hospital of Manhattan was open to visitors on October 9, and will be formally dedicated on October 16.

The Alvarenga Prize.—The College of Physicians and Surgeons of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about $300, will be made on July 14, 1922, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Information with reference to the details of the competition may be obtained by writing to Dr. John H. Girvin, Secretary, 19 South Twenty-second Street, Philadelphia, Pa. The Alvarenga Prize for 1921 has been awarded to Dr. John W. Churchman of New York City for his essay entitled "Selective Bacteriostasis of Gentian Violet."

Dr. Lewis A. Coffin has removed his office to the Medical Chambers at 114 East Fifty-fourth Street, New York.

Dr. Marcus A. Newell, formerly of Sheridan, Wyoming, has removed to New York City, and is associated with Dr. Edward Wallace Lee, 616 Madison Avenue.

Dr. Clarence L. Starr, chief surgeon at the Hospital for Sick Children, Toronto, has resigned his post to accept the position of Professor of Surgery at the University of Toronto.

Harvey Society Lecture.—Dr. C. R. Stockard, Professor of Anatomy, Cornell University Medical College, will deliver the First Harvey Society Lecture at the New York Academy of Medicine, Saturday evening, October 22, 1921, at 8:30 o'clock. His subject will be "The Significance of Modifications in Body Structure."

Gifts to Columbia University.—Columbia University announces the acceptance of gifts to the amount of $37,209.32, among which are the following of medical interest: The Borden Company gave $10,000 for research in food chemistry. Mrs. Elizabeth Coolidge gave $2,400 for the maintenance of the Coolidge Fellowships in medicine. Dr. and Mrs. Harold Lee Meierhof have given $1,000 to establish the Harold Lee Meierhof prize in the department of pathology.

Prize for Medicinal Cure of Cancer.—The Cosmopolitan Cancer Research Society of Brooklyn, chartered by the State in July, announces a prize of $100,000 provided by an anonymous donor for a "medicinal" cure for cancer. The objects of the society are to provide treatment to cancer patients unable to pay and to investigate various cancer remedies. The work of the society is supported by private contributions.

The American Academy of Ophthalmology and Oto-Laryngology will hold its twenty-sixth annual meeting in Philadelphia, October 17-22, 1921. In addition to the scientific sessions various clinics and exhibits will be provided for the members and guests of the society.

Openings for Physicians in the U. S. Public Health Service.—Examinations of candidates for entrance into the regular corps of the U. S. Public Health Service will be held November 14, 1921, at Washington, D. C., Chicago, Ill., and San Francisco, Cal. Candidates must be between 22 and 32 years of age, and graduates of a reputable medical school. They must pass satisfactorily

oral, written and clinical tests before a board of medical officers. Successful candidates will be recommended for appointment by the President with the advice and consent of the Senate. Requests for information or permission to take this examination should be addressed to the Surgeon General, U. S. Public Health Service, Washington, D. C.

Obituary Notes.—Dr. EDWARD LELAND MOONEY of Syracuse, N. Y., died suddenly of heart disease on October 1, at the age of sixty-two years. He was graduated from Michigan University School of Medicine in 1886, and was a fellow of the American College of Surgeons. He was a member of the American Medical Association, the Onondaga Medical Society, and the Syracuse Academy of Medicine. He was physician to the Hospital of the Good Shepherd and on the staff of the Syracuse Free Dispensary.

Dr. BENJAMIN F. MILLINGTON of South Londonderry, Vt., died following an operation in a Brattleboro hospital on September 21, at the age of sixty-one years. He was graduated from the University of Vermont College of Medicine in 1886.

Dr. ISABELLE MATHISON RANKINE, formerly of Brooklyn, N. Y., died in Tappan, N. Y., on September 26. She was graduated from the New York Medical College and Hospital for Women in 1882, and for many years was on the visiting staff of the Eastern District Homeopathic Dispensary.

Dr. WALTER JOHN WHITEHOUSE, Jr., of Marcus Hook, Pa., died of nephritis at the Chester Hospital on September 19, at the age of thirty-nine years. He was graduated from the Medico-Chirurgical College, Philadelphia, in 1905. He was an assistant surgeon in the United States Public Health Service and for eleven years was attached to the Quarantine Station at Marcus Hook.

Dr. JOHN W. WARREN of Snyder, Tex., a graduate of the Kentucky School of Medicine, Louisville, in 1891, died about September 8, at the age of sixty-four years.

Dr. AARON TILZER of Portland, Ore., died on September 15, at the age of fifty-six years. He was graduated from the University of Oregon Medical School in 1897.

Dr. JOHN W. DENISON of Parsons, Pa., a graduate of the University of Michigan Medical School in 1885, died on September 18, at the age of sixty years.

Dr. JOSEPH KERR WEAVER of Norristown, Pa., a graduate of Jefferson Medical College, Philadelphia, in 1867, died suddenly of cerebral hemorrhage on September 30, at the age of eighty-three years. He was a fellow of the American Academy of Medicine and surgeon general of the National Guard of Pennsylvania for a number of years under five governors. He was one of the founders of the Norristown Hospital.

Dr. JOSEPH G. SAVANNAH of Farmingdale, N. J., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1917, died on October 2, at the age of thirty-four years. He was connected with the Tuberculosis Preventorium at Farmingdale, and served during the World War in the Medical Corps of the United States Army. He was also a member of the staff of the Ann May Memorial Hospital at Spring Lake, N. J.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, September 23, 1921.

Influx of Medical Students.—When the medical schools open here in October there will be another very large influx of medical students, and the resources of the schools will be tested to the utmost. The president of the General Medical Council, Sir Donald MacAlister, in his opening address at the May session, drew attention to the overcrowding of the profession. However, this warning appears to have carried no weight, although, of course, it was absolutely justified. It must be borne in mind that the education of a medical man is nowadays an extremely expensive affair and the prizes of the profession are few. At least £1,500 is required to carry a medical student through his course, and his chances of making money subsequently are meagre in the extreme, for he may consider himself fortunate if he is able to gain a comfortable livelihood. With overcrowding, competition is keen, even ruthless, and the less persevering, or sometimes the most scrupulous, must inevitably go to the wall. A marked feature of this somewhat inconsiderate rush to join the ranks of the medical profession is the increasing eagerness of women to become qualified to practise the healing art. The war undoubtedly has had much to do with this innovation. Women workers in the war zones and outside these zones naturally witnessed the exercise of the surgeon's and physician's craft on a wide scale, and many of them were impressed favorably by it. Moreover, the exigencies of the war were responsible for numerous appointments of qualified women as internes in hospitals, appointments which had not been open to them previously — that is to say, except on very rare occasions. It may be added that in these positions women acquitted themselves remarkably well—in some instances with conspicuous success. Now that the barrier of custom has been partially broken down, women compete with men for the resident appointments which are open to both. Again, the sphere of women's usefulness in medicine has of late been greatly widened. Research, for which women are frequently peculiarly well adapted, offers good opportunities. Maternity and child welfare work, the latter especially, provide other openings, and certain appointments in the public services are available to women. Lastly, there is quite a considerable demand for the services of medical women by the missionary societies, as in some countries, India for example, religion and caste do not admit of the medical attendance of the majority of the female population by men. It will thus be seen that various causes have combined to increase the number of medical students in this country and this in face of the fact that the nature of medical practice is undergoing a great change, and that the future of the medical profession, if certain radical reformers have their way, looks by no means rosy.

Public Medical Service Demanded by the Friendly Societies.—The National Conference of Friendly Societies is holding its sittings at the

present time. In the opening address the president spoke of health questions and the medical profession, saying that, so far as the valuation surpluses were concerned, there appeared to be a great diversity of opinion as to the form the additional benefits should take. Personally he thought this was regrettable. Instead of dabbling with the question of health through the medium of extraneous benefits, they ought to concentrate their attention on securing a thorough, all-embracing public health service under the Ministry of Health. This, of course, would include the public health service which they had demanded on many occasions. The speaker went on to say that it was patent that they were not getting the value for the enormous sum paid to the medical profession, a total nearly as great as the amount spent on sickness, disablement, and maternity benefits. The economists in the House of Commons, when discussing the administration of health insurance, should bear this point in mind. No one was satisfied, unless it was the doctors, with the present medical service. A proper medical service must be correlated with hospitals, nursing, and other services. A fine nucleus existed already in the present public health services, and it was in the extension of these that they must look for the solution of the preventive side of the work. Many of the diseases today were due to preventable causes, and if much disease was to be eradicated they must turn to the child and see that it was brought up and trained under healthy and sane conditions. The speaker said more in a similar vein, but enough has been quoted to show the trend of his argument. He, like most of the members of the Friendly Societies, desired the nationalization of the medical profession, whereby the profession would lose its independence and its members would be more or less at the beck and call of their patients, who, in turn, would perhaps be guided by opportunist politicians.

Suggested Reduction of Panel Doctors' Pay.—As a straw showing which way the wind is blowing, the suggested reduction of the capitation fee for medical services under the National Health Insurance Act is interesting. The matter was discussed at a meeting of general practitioners called by the Medical Practitioners' Union. The following resolution was placed before the meeting: That this meeting of panel practitioners affirms that the eleven shillings fixed recently by arbitration is inadequate to cover the services rendered, and will tolerate no reduction whatever.

Investigation of the Causes of Dental Decay.—The Medical Research Council, in consultation with the Ministry of Health, has appointed the following committee to investigate the causes of dental decay: Prof. W. D. Halliburton, M.D., F.R.S. (chairman); Norman G. Bennett, M.B.; Leonard Colebrook, M.B.; I. M. Hamil, M.D.; Sir Arthur Keith, M.D., F.R.S.; Mrs. Edward Mellanby, J. Howard Mummery, M.R.C.S.; C. J. Thomas, M.B. Professor Halliburton is the professor of physiology at King's College, London; Doctors Bennett and Howard Mummery are very well known in the dental world, Sir Arthur Keith is the Curator of the Museum of the Royal College of Surgeons, Mrs. Mellanby, together with her husband, Professor Mellanby, has done a great deal of valuable work on rickets and the dietetic problems associated with it; Doctor Colebrook is a bacteriologist who has been associated with Sir Almroth Wright at St. Mary's Hospital, and is now assistant to the bacteriological department of the Medical Research Council; Doctor Hamil is on the staff of the Ministry of Health, and Doctor Thomas on that of the London County Council.

International Dental Exhibition.—An international dental exhibition was held a week or so ago in London and appears to have been a success. A vast amount of ill health and even of disease are attributed to focal infection, and, while the sinister influence of decayed teeth and infected gums may have been exaggerated, there is no doubt that both as primary and contributory causes they are important factors. The investigations into the national health which were an outcome of the war afforded overwhelming evidence that the condition of the teeth of the population of Great Britain generally was deplorable. Consequently, in order to provide for the health and efficiency of the nation at the present time and in the immediate future, the services and care of the dentist will be more greatly in request than in the past. The exhibition gave convincing evidence of the progress that has been made in dental treatment. To the mass of the population the dentist is regarded merely or mainly as a puller of teeth, as he was regarded in the Middle Ages. However, it may be pointed out and strongly emphasized that the population at large should be taught that the chief function of the scientific dentist is not extraction but conservation of teeth. An individual is immensely handicapped and his life is darkened if he has lost all or most of his teeth, no matter how good the substitutes may be. It is to be hoped that the investigations of the committee of the British Medical Research Council, referred to above, may result in discovering at least some of the principal causes of dental decay, for unless the basic cause is known successful treatment is practically impossible.

Infant Mortality in London.—Infantile mortality in London increased considerably during July and August, owing to diarrhea and enteritis. During June the average death rate from these two causes was 11 per 1,000. For the seven weeks ending August 27 the figures were 30, 29, 52, 65, 103, 154, and 142. This extremely high death rate must be largely ascribed to the phenomenal drought.

LETTER FROM SWITZERLAND.

(From Our Own Correspondent.)

GENEVA, October 1, 1921.

Cancer Increasing.—Attention is being called at present by many competent observers to the increase which, year by year, has been taking place in the incidence of cancer. This is not a new warning, as those who have followed the history of this dire morbid process are aware. Hitherto, however, it has been possible to meet the figures given to prove increase, by arguments of a very cogent character. For one thing we were entitled to expect

that perfected methods of diagnosis would discover instances of the disease which, without them, must have passed unrecognized. No one was in a position to deny that both physicians and surgeons had, during the last few decades, vastly increased the number of their instruments of precision; new tests had been devised, new data ascertained, novel conceptions built up. To suggest that with all this added knowledge and power at their disposal physicians would not more easily and rapidly detect and recognize the disease appeared on the face of it absurd. Nor was this the only argument against acceptances of the statements of increase. It was pointed out that the expectation of life in Western Europe has been steadily enlarging; many more people than formerly would thus reach the "cancer age." This fact would account for a proportion of the recorded cases.

These considerations, unfortunately, can no longer be accepted as a complete answer to the fears which are now being expressed on the Continent and in England. Regardless of the fact that our powers of recognizing cancer have not materially improved during the past decade, and that the expectation of life has not been increased to any extent, the cancer increase progressively continues. Indeed the very arguments which at one time appeared to offer assurance tend now to support the evil tidings. For improved diagnostic methods must necessarily imply earlier treatment, and we have been told over and over again that the one certain and hopeful thing about malignant disease is that, if it is recognized early and dealt with radically, it can, in many instances, be permanently eradicated. Most surgeons believe that cancer is curable if surgical treatment be resorted to in time, hence this circumstance should have tended to reduce the mortality. But the mortality has risen and not fallen. Moreover, the greater expectation of life does not by any means imply that more people reach the cancer age. It may simply mean that fewer people die in infancy and adolescence.

Consequently there would seem to be but small doubt that in Europe, and probably also in America, at a time when almost every other important disease is becoming less of a menace, cancer is slowly progressing. That environment plays a very small part indeed seems evident from the fact that the well-to-do suffer equally with, or even more severely than, the poor. Food may conceivably be a factor and many scientific men have advanced this view. It has been stated by some that cancer is unknown within the Arctic Circle, others maintain that it represents an after-result of precedent infections among which syphilis stands preeminent.

These views are quite indefinite enough to warrant us in refusing any adherence to them, with the possible exception of syphilis. Nor shall we consult our best interests by taking stock in those who claim the discovery of cures or nostrums. Both radium and the *x*-ray have strong advocates, and both have certainly succeeded in particular instances and as certainly lamentably failed in others. The truth would seem to be that treatment of the local condition is often unsuccessful, and a great amount of work remains to be done before any sort of conclusion can be reached. The present situation of the cancer problem is far from encouraging.

Progress of Medical Science.

1. Two Cases of Carcinoma of the Kidney, One with Invasion of the Vena Cava and Right Heart. William S. Quinland.
2. Congenital Atelectasis. Samuel A. Cohen.
3. Calculus in the Submaxillary Gland. Frederick Sherman Hopkins.
4. The Mesotherapor for Ear and Nose Treatment. James Taylor, Jr.

1. Two Cases of Carcinoma of the Kidney, One with Invasion of the Vena Cava and Right Heart.—William S. Quinland reviews the literature and quotes a case reported by Newman (*Glasgow Medical Journal*, 1896, xlv, 179), which resembled the first case herein recorded. In this case, a man fifty-five years of age, the anatomical diagnosis was carcinoma of the kidney with metastases to the liver, heart, lungs, adrenals, lymph nodes and mesentery. There was tumor thrombosus of the inferior vena cava and right auricle, chronic passive congestion of the liver and lungs, chronic nephritis, chronic bronchitis, atrophy of the spleen and arteriosclerosis. A microscopical study of these tumors indicates that they are primarily of renal cell origin because of the papillary arrangement of the cuboidal cells much like that of adenoma of the kidney. Also the findings of groups of typical adrenal cells so easily differentiated from the tumor cells present in the adrenal gland, make it more apparent that the tumor must be of renal origin and not a hypernephroma. The tumor in Case 2 seems to be an adenocarcinoma of renal origin which has in places taken on the characteristics of a more malignant form of carcinoma with a loss of glandlike structure, and the possibility of producing subsequent metastases. Although there is nothing original in the opinion that carcinoma arises in the first instance from renal epithelial cells, one seldom sees a case in which the structure of the original tumor and its metastases approach so nearly the structure of adenomata of renal cell origin. The relatively low statistics of cancer of the kidney are due to the many difficulties in making a correct diagnosis of the disease and to the tendency of classifying these tumors as hypernephroma. Invasion of the inferior vena cava and right heart is of comparatively rare occurrence, such cases being diagnosed only at autopsy. The frequency with which the liver is affected in such cases as compared with the spleen and other organs makes it possible that invasion of this organ is effected by way of the hepatic veins. It is of interest, though not surprising, that carcinomata of renal cell origin may show many of the characteristics of malignant hypernephromata of adrenal origin, such as a marked tendency to invade the renal vein, since the cells from which they originate are embryologically so similar.

Congenital Atelectasis.—Samuel A. Cohen states that atelectasis even to a considerable degree may be found at necropsy in an infant who in life presented few or no symptoms. Most hospital cases show a small infant, with cold extremities, a feeble cry or a failure to cry, in some instances even after having been pinched. Not infrequently there is a dusky color or cyanosis. A large percentage of these babies are too weak to suckle. Physical examination usually shows a feeble, cold, puny baby, skin and mouth dry, depressed fontanelle, and subnormal temperature. Local examination of the chest may reveal nothing but poor resonance throughout. Comparison of the two sides of the chest, if both lungs are equally affected, is of no value. Often both tops and bases will be impaired. There may be increased resistance and marked dulness over the affected areas and hyperresonance over the rest of the lungs. Auscultation may sometimes reveal medium coarse râles, though more often fine crackles or showers are heard. Vesicular breathing is most frequent. There may, however, be any type of breathing. The more serious cases attended with collapse and particularly with subnormal temperature have a slow pulse from 70 to 90. Evidence based on a series of cases shows that diagnosis is made more frequently on symptoms than on physical signs. In over half the cases examined no evidence of atalectasis was found

by physical examination of the chest. The *x*-ray, however, has been of great help in detecting congenital atelectasis, having led to the diagnosis in about half the cases. The roentgenogram very often shows a broad shadow at the hilus, rarely clear cut and sharply defined, while the peripheries of the lungs are usually clear. Any treatment that causes the infant to breathe more deeply should be instituted, provided it does not result in too great expenditure of the infant's energy. Effort should be directed to increasing the infant's vitality by good hygiene and proper feeding. Congenital atelectasis is often preventable if mothers would see to it that their infants are made to cry in the earlier weeks of life. Occasionally the attending physician fails to see that the baby cries sufficiently. Crying is the only source of exercise during the early days of life. It is not cruel if the baby does not cry to make it cry.

2. The Treatment of Carbon Monoxide Poisoning.—Howard W. Haggard and Yandell Henderson state that carbon monoxide poisoning is so common in modern communities that the death rate on its account is comparable to diseases which, if not the commonest, rank close to the commonest. The therapeutics of carbon monoxide asphyxia are, therefore, important. They have recently worked out a standard for exposure to carbon monoxide which may be expressed by the rule: Multiply the time of exposure in hours by the concentration of the gas in parts per 10,000 of air. If the product equals 3 or less, there is no appreciable physiologic effect. If it equals 6, there is sometimes slight malaise. If it equals 9, a headache or some nausea is produced in most people. If it equals 15, the conditions are dangerous for anything beyond brief exposure. If it is more than 15, they are extremely dangerous even for brief exposure. When a man or animal is asphyxiated by illuminating gas the course of events is as follows: As the blood gradually takes up more and more carbon monoxide, the increasing oxygen deficiency induces an augmentation in the volume of air breathed per minute. This, of course, augments the absorption of gas; but it has another effect, it washes the carbon dioxide out of the body. Now, the normal stimulus for breathing is the carbon dioxide, which the blood carries to the respiratory center. A time comes when the lack of carbon dioxide has progressed to a point at which respiration stops, for lack of this stimulus. If, however, before death the subject is removed from the gassing chamber to fresh air, but is not further treated, the condition for the next half or three-quarters of an hour is one of extremely feeble breathing. During this period little carbon monoxide is eliminated. The condition of acute asphyxia continues and is exacerbated by the poor respiration. At this time the greatest injury is wrought to the nervous centers by lack of oxygen and the conditions in the body are not appreciably better than before removal from the gassing chamber. If, however, 8 or 10 per cent. carbon dioxide is added to the oxygen, an altogether different result is obtained. Under inhalation of this mixture breathing is quickly restored to normal, or more than a normal amount. With the aid of this full ventilation of the lungs, the mass action of the oxygen in the alveoli quickly displaces carbon monoxide from the blood. Certain other changes also occur in the blood, dependent upon the restoration of its carbon dioxide, and the recall of alkali from the tissues. This treatment, the authors believe, is the long sought and ideal therapy for carbon monoxide poisoning, but its application will require a rather specialized apparatus. Such an apparatus was devised by them for oxygen inhalation by gassed soldiers during the war, but it did not come into extensive use. Oxygen containing 8 per cent. carbon dioxide is not yet on the market. Developments in these matters are under way. For miners gassed after dust explosions, and for men overcome during rescue and salvage operations, this treatment holds out hope for diminishing fatalities. It is not so probable that the overnight case of illuminating gas poisoning will be as easily helped, since the crucial feature of the proposed inhalation therapy is the termination of the tissue asphyxia at the earliest possible moment.

3. The Prevention of Simple Goiter in Man.—David Marine and O. P. Kimball review the experimental physiology which demonstrates the underlying principles of goiter prevention and call attention to the ease with which they may be applied. The results of their two and one-half years' observations on school girls in Akron, Onio, were as follows: Of 2,190 pupils taking two grams of sodium iodide twice yearly, only five have developed enlargement of the thyroid; while of 2,305 pupils not taking the prophylactic, 495 have developed thyroid enlargement. Of 1,182 pupils with thyroid emargement at the first examination who took the prophylactic, 773 thyroids have decreased in size; while of 1,048 pupils with thyroid enlargement at the first examination who did not take the prophylactic, 145 thyroids have decreased in size. Klinger has recently reported even more striking curative results in the school children of the Zürich district. It has been demonstrated that simple or endemic goiter in man may be prevented as cheaply and as simply as in the lower animals by the administration of three to five mg. of iodine twice weekly over a period of a month, and repeated twice yearly. There are no dangers worthy of consideration associated with the administration of the quantities of iodine used by Klinger or the writer. Simple or endemic goiter develops most commonly during fetal life, around the age of puberty, and during pregnancy, and any plan which provides for its control during these three periods of life will practically eliminate endemic goiter. The prevention of goiter of childhood and adolescence should be a public health measure, best administered through the schools in order to combine the important additional matter of education. The prevention of goiter is not only good preventive medicine, it is better preventive surgery.

5. Hypertension with Minimum Renal Lesions.—Eli Moschcowitz emphasizes the thesis which he has brought forward in former papers that no mechanistic interpretation can explain how hypertension can result from any variety of destructive lesions of the kidney, experimental and otherwise, and that all clinical and experimental evidence seems to prove that arterial disease, when associated with hypertension, is the result rather than the cause of hypertension. In the present communication five cases are reported in which hypertension and other clinical evidences of nephritis were present, although the kidney showed but slight lesions, certainly less than conventional teaching led one to expect. These cases, which the writer's experience and the study of reported observations leads him to believe are not at all uncommon, show that clinical and postmortem nephritis are by no means synonymous, and that above all, as he has previously insisted, the presence and the degree of hypertension bear no relation to the extent of the lesion. These observations lend no support to the belief that the hypertension of chronic nephritis is of renal origin, but are not inconsistent with the thesis that hypertension is one of the factors in producing nephritis, better termed arteriocapillary fibrosis. Evidence is adduced to show that arteriocapillary fibrosis is merely the localized and prominent manifestation of a generalized capillary and vascular disease. This accounts for

the associated clinical phenomena referable to other organs in hypertensive disease, e. g. brain, aorta, heart, pancreas, arteries, etc. In this conception arterial disease and arteriocapillary fibrosis are not maladies which bear any mutual relation to each other, but are contemporaneous reactions to the same insult. Evidence is again submitted that the lesions of the secondary contracted kidney (malignant contracted kidney), in which hypertension is present, and the decrescent kidney (benign contracted kidney, arteriosclerotic kidney, primary contracted kidney), in which hypertension is slight or absent, are morphologically, to all intents and purposes, identical. To explain the pathogenesis of the latter form of contracted kidney, the hypothesis is submitted that whereas in the secondary contracted kidney the most important if not the main factor in its production is vascular hypertension, in the primary or benign contracted kidney it is vascular tension. Hypertension according to this conception is merely an exaggerated phase of a normal functional process. The functional changes in the organism are consequent on compensatory mechanisms.

9. Hepatoduodenostomy, with Observations on the Lyon-Meltzer Method of Biliary Drainage.—Arthur D. Dunn and Karl Connell describe experiments carried out on a patient without a gallbladder or common duct which show that the assumption is not necessarily true that the B, or dark, viscid fraction of the A B C magnesium sulphate bile sequence represents gallbladder bile and that we are not as yet justified in localizing disease in the biliary tract on evidence afforded by the Lyon-Meltzer method of bile segregation. Their experiences suggest that the following possibilities may be the answer to the A B C phenomena in the Lyon-Meltzer test: First, an enterohepatic circulation of magnesium in which the latter, carried to the liver in the portal blood, acts directly on the liver as a cholagogue, *producing a bile flow rich in pigment*, or, second, a destruction of red corpuscles, possibly by the magnesium ion, somewhere in the portal system, resulting in sudden dumping of an increased quantity of blood pigment on the liver, which reacts to this stimulus by an increased output of bile rich in pigment.

5. Studies from the St. Andrew's Institute of Clinical Research. I. Present State of Medical Knowledge Regarding the Diseases Common Among the People.—Andrew Rowand publishes the outcome of an inquiry in what proportion of cases met with in general practice it is possible to arrive at a diagnosis. There were in all 974 cases, 314 Institute cases, and 660 private patients. Of this number 275 cases were diagnosed, 38.21 per cent. being Institute cases and 28.23 private cases. This experience serves to emphasize the fact that the differentiation of disease is lamentably inadequate and that some new method of classification must be found to save us from the increasing complexity and confusion which are the despair of the medical practitioner. Sir James Mackenzie's classification has been extended to include six groups, not in order to amplify it as a classification of diseases, but to form a classification of the cases with which a doctor has to deal in his ordinary work. The classes are as follows: *Class* I. In this class the symptoms enable the primary diagnosis to be made. The standard example of diseases of this kind is conjunctivitis; other examples are tuberculosis, dysentery, syphilis, malaria, diphtheria, ringworm. *Class* II. In this comparatively small class are included diseases in which, while the symptoms are recognized, the injurious agent has not been recognized, though its nature can be inferred. Examples of this class are measles and scarlet fever. *Class* III. This is a large group and includes diseases with a well recognized group of symptoms, but where the nature of the agent is not recognized. Examples of this class are asthma, acidosis, epilepsy, herpes zoster, hysteria, and recurrent vomiting. *Class* IV. In this class are placed end-results, by which is meant not the concluding stages of known progressive disease, but conditions of permanent damage to organs or tissues, the original noxious agent, whether known or unknown, having ceased to be of importance and the damaged organ itself giving rise to the symptoms of disease. Examples of this group are a variety of heart affections, arteriosclerosis, malignant disease, and senility. *Class* V. In this class are included cases in which a definite local lesion or morbid condition exists, giving rise to symptoms, the noxious agent causing the mischief being unknown, and no uncoordinated symptoms being present, so far as can be determined, indicative of more widespread disease. The lesion may be visible or inferred from the symptoms observed. Here watch must be kept for more generalized symptoms. Bronchitis may be taken as a typical instance of this group. *Class* VI. This class contains the cases showing a number of uncoordinated symptoms with no recognizable common cause. This constituted the largest group of cases in the series studied, being 43.03 per cent. of the Institute cases and 53.03 per cent. of the private cases. This large group of undiagnosable cases presents an invaluable field for study.

6. The Psychopathology of Pulmonary Tuberculosis, with Special Reference to Treatment.—D. G. Macleod Munro points out that although there is probably no disease in which there is such close correlation between body and mind, little attention has been paid to this intimacy of association. There are certain well marked features of the psychic state of the average phthisical patient. In general these may be said to indicate reversion to the congenital or infantile type, and such suppression and modification of these as may have resulted from environment and education is largely abolished. Many become introspective, selfish, egocentric, weak-willed, and lacking in self-control, though not a few become morally stronger as a result of the self-abnegation called forth in the course of the long battle for health. In those of ordinary attainments there is at times a species of mental excitation with an added keenness of intellect of which no adequate explanation has been offered unless we accept it as resulting from prolonged intoxication set up by the endotoxins of the bacillus. In those of literary and artistic attainments this psychic and mental excitation has been found to occur in marked degree, and in the long and tragic roll of men and women of genius who have suffered from this disease nothing is more striking than the fact that the creative powers of the mind have been at their highest at a time when the disease was active and progressive. With the exception of the functional neuroses there is perhaps no disease in which the susceptibility to suggestion is so high as in pulmonary tuberculosis, and in few diseases can this suggestibility be utilized so patently for good or evil. The cures claimed for a large variety of drugs used in the treatment of tuberculosis have their basis in suggestion. We no doubt have in psychotherapy a remedy for the alleviation at least of many of the distressing accompaniments of this disease which may react favorably on the purely physical side of the disease. When a patient is admitted to a sanatorium, in addition to the ordinary history of the case, the fullest details of the patient's family and mental history should be sought and such treatment as is found necessary after due observation, either in the form of mental exercise and relaxation, or more specifically as psychotherapy, and in certain cases psychoanalysis, should be duly instituted. In the larger institutions for the treatment of tuberculosis one at least of the medical staff, Dr. Munro contends, should possess the necessary qualifications for psychotherapeutic treatment.

2. A Statistical Study of Three Thousand Cases of Mental Disease.—Henry Daspit presents these data on three thousand cases of mental disease purely in the light of a preliminary report. He believes the figures presented offer a better demonstration of conditions as to mental health in the community than would be shown by similar data from the State Hospital, since the City Hospital for Mental Diseases, at which institution the data were collected, receives all doubtful cases apprehended by the police, cases transferred from the courts for observation, etc. The summary of the data presents types of mental disease, classified as to ages when coming under observation, sex, and color, and the tendency of the various types to marriage, and thus to add to our future burden. Among the 3,000 cases were 213 senile psychoses, including all forms, with the exception of frank involutional melancholia. They are equally distributed as to sex and about 50 per cent. are widowed. General paresis shows the largest number of any single group, 443. White males are in the proportion of about 4 to 1 as to white females. Colored males about 2 to 1 as to colored females. More than 50 per cent. were married, and at least 80 per cent. of these were married after having acquired syphilis. Under cerebral syphilis are 50 cases in which cerebral lues proved to be the essential factor in the psychosis. The majority of definite alcoholic psychoses occurred in early life in the unmarried, and totaled 140. Since national prohibition has come the admission of an alcoholic psychosis is an event. There were but 24 cases of pellagrous psychoses. Of 288 manic depressives, 163 were married. Quite a few had given birth to children after discharge from some hospital care necessitated by a previous episode. Ninety-two males and 192 females comprised the group. The cases of involutional melancholia, after eliminating manic depressive association, numbered 118, there being about 3 females to each male. Dementia precox stands second on the list with 325 cases, 213 males and 112 females. Only 58 were or had been married. The group of paranoic states totaled 131; that of epileptic psychoses 151, the males predominating. Among these it was noted that there was a greater proportionate tendency to marry. The constitutional psychopathic inferiors numbered 229, and mental deficiency 240. These offer an entirely different problem from the psychoses and call for concerted action which will lead to an institution to meet their special needs.

7. Hare-Lip and Cleft Palate: A War Influence. J. L. Aymard.

1. Acute Pleural Empyema.—Henry Wade expresses the opinion that results in the treatment of empyema have not been entirely satisfactory. He believes that many valuable lessons may be learned by comparing the pathology of suppuration within the pleural cavity, the abdominal cavity, and such a joint cavity as the knee-joint. As the result of such comparison he makes the following suggestions: (1) A combined cytological and bacteriological examination of the fluid withdrawn should be more widely employed, as offering the prospects of affording fuller and more accurate data on which to found our operative treatment. (2) Suppuration within the pleural cavity is especially suitable for treatment by methods which obviate the necessity for opening the chest, or by methods where an immediate or early closure after it has been opened are carried out. (3) The value of the treatment by aspiration alone should be again carefully reviewed. (4) The value of methods where, after aspirating the content, an antiseptic is introduced, such as Murphy's method, where 2 per cent. formalin in glycerin is introduced, should be further considered. (5) Where simple drainage is practised the ideal opening is not only one which allows free escape of the purulent content at the time, as when a rib is resected, but it should be such as will readily seal itself off when the tube is withdrawn, as when minor intercostal thoracotomy is performed. (6) The benefits to be derived from a free opening of the pleural cavity by major intercostal thoracotomy warrant its employment in cases which give promise of developing into chronic and persistent cases. (7) The value of disinfection and immediate closure in these cases should be more fully tested. (8) The Rutherford Morison technique is the best at present available for carrying out the same.

2. Intussusception: An Analysis of Thirty-six Cases.—G. H. Edington gives a summary of these thirty-six cases which leads to the following conclusions: (1) There was in this series a marked preponderance in males, the frequency being three and a half times as great as in females. (2) The majority (68 per cent.) of the cases occurred in the first year, and of these the average was 6.15 months. (3) More than one-third of the cases were of the ileocecal (including ceco-ileocecal) variety. (4) Visible proof of etiology was not found at operation. (5) The death rate of 40 per cent. depended largely on the length of interval before operation, and secondary to this, on gangrene; it was highest in ileocecal cases. (6) Resection gave invariably fatal results.

3. The Best Method of Operative Approach in Acute Appendicitis.—Hamilton Balance advocates the use of an oblique incision over the iliac fossa in preference to the midline or right semilunar line incision in cases of acute appendicitis operated upon during the first two or three days of illness. The incision is made in the same line in the external oblique, the internal oblique, and the transversalis muscles. There are certain conditions of fundamental importance which should be remembered when an operation on a case of acute appendicitis is undertaken. These are that the shortest route should be chosen to the infected area, and the fullest possible view obtained of it; that the intestines and other abdominal viscera around this area should be disturbed as little as is consistent with efficient treatment of the infection; that the operation should be performed as rapidly as possible, and that the appendix in all cases, with very few exceptions, should be removed. The oblique incision fulfills these conditions and admits of being extended at either end. The writer has used this incision for twelve to fifteen years and has never known it to cause a ventral hernia.

1. Chronic Myocarditis and Its Management.—Henry A. Christian states that chronic myocarditis in his wards, into which children are not admitted, is a trifle more frequent than any other form of chronic cardiac disease. It is a condition frequently unrecognized, and often given other diagnostic names. Most often, perhaps, it is called mitral insufficiency. In reality mitral insufficiency in the sense of organically diseased mitral leaflets is very rare except in association with a deforming change which produces both stenosis and insufficiency of the valve, and this rarely develops after 40, the age after which chronic myocarditis is commonest. A great deal of confusion would be saved if the term mitral insufficiency were dropped altogether as a diagnostic term. When you make that diagnosis in the organic sense you are wrong in about 99 per cent. of the cases. When there are evidences of cardiac incompetence, usually the mitral valve leaks because the heart muscle is insufficient, and so the murmur one hears indicates myocardial disease. This should be diagnosed as chronic myocarditis. The systolic murmur is of very little diagnostic or prognostic significance. Chronic myocarditis is diagnosed mainly by the evidence of a weakened circulation apart from the heart as shown in various portions of the body by symptoms and physical signs. The symptoms are those you get when a normal heart is made to do too much work. In almost all patients of this group cardiac symptoms have developed after 40 and a history of true rheumatism is lacking. Except for a syphilitic aortitis causing aortic insufficiency practically all cardiac murmurs in those with cardiac symptoms developing after 40 arise from myocardial, not from valvular changes. Treatment in myocarditis as a rule is very satisfactory and rests on three main reliances: (1) Rest, digitalis, and diuretics. The practitioner is apt to err in his idea of rest. It must be complete and maintained. In attaining rest morphine frequently is of inestimable value. Rest means that exertion be reduced to the lowest possible minimum. Digitalis in this group of cases is capable of accomplishing wonders. There is but one essential in digitalis therapy: know what the results are that you should get and give sufficient of the drug to get these results. The essayist has never experienced a difficulty in obtaining satisfactory digitalis effects from untreated powdered leaves, made into pills, if the leaves are potent. If you get good results from a certain supply of digitalis leaves, ask your druggist to dispense that leaf to your patients until it gives out, and when he gets a new supply to send you a sample to test before you allow him to fill your digitalis prescriptions. Local cooperation in this matter between fellow practitioners would be of great value. As a diuretic theophyllin gives the best results, though theobromin sodiosalicylate gives results almost as good. The best way to use them is to give them after two days of digitalis therapy, in two doses, one early in the morning and the other at noon time; of theophyllin, 3 grains, or of theobromin sodiosalicylate, 7½ grains, and repeat this dosage on the third day if necessary. Vigorous catharsis should be omitted from the treatment of cardiac cases. Fluids should be moderately restricted. The course of treatment should not be ended until the patient is free from edema in his legs, over the sacrum, and at the bases of his lungs.

2. The Treatment of Neurosyphilis.—Albert Keidel urges the importance of recognizing this condition in its incipiency. It is now known that the central nervous system is invaded by the treponemas in from 25 to 35 per cent. of the cases. The organisms reach the vital center very early in the course of the disease, perhaps even before the development of the primary lesion, but at the latest during the period of general invasion. Lumbar puncture is the only means for the early diagnosis of asymptomatic neurosyphilis, and as its significance has been tragically overlooked by the major portion of the profession in dealing with syphilis, Keidel suggests its general employment by the profession at large as a means of cutting down the incidence of symptomatic neurosyphilis. From the standpoint of our present knowledge he thinks it a dereliction from duty for any physician to neglect this early investigation of the cerebrospinal fluid. It is not only valuable in that it affords an opportunity for aborting neurosyphilis, but subsequent punctures will indicate the progress made and determine those cases which fail to respond favorably. It must be remembered that a negative spinal fluid at one period of infection does not preclude the possibility of a subsequent invasion of the central nervous system, particularly when the early treatment has been inadequate. It is not an extravagance to say that syphilis is the most inadequately treated disease of our day. The responsibility for this lies largely with physicians, and cannot be terminated by the patient's inability to pay. The therapy of cerebrospinal syphilis is that of general syphilis reinforced by whatever special procedures best subserve the fundamental requirements. The writer's plan of treatment consists of courses of arsphenamin intravenously alternating with courses of mercury inunctions. Progress is estimated by studies of the blood at weekly and monthly intervals. The first lumbar puncture is made after treatment is begun, and if negative findings are obtained is not repeated until the end of treatment is reached. Treatment is continued for one year after the blood Wassermann becomes negative. If, under this routine management, abnormalities in the spinal fluid persist to the extent that no further progress results intraspinal therapy is made necessary by the inaccessibility of foci of infection to substances in the blood stream. Among the later cases treatment by the ordinary routes will often succeed in obliterating serologic abnormalities, with marked clinical improvement, but the possibility of isolated foci of infection remaining undisturbed in areas not involved in the clinical picture makes the addition of intraspinal therapy desirable.

7. Kondoleon Operation for Elephantiasis; a Report of End Results.—W. E. Sistrunk reports that this operation has been performed 32 times at the Mayo Clinic. He calls attention to the fact that, while on account of our earlier teachings, filariasis is often thought of in connection with elephantiasis the majority of patients in this country in whom the disease is seen are found to be free from filarial infection. The operation consists of a long modified eliptical incision on the inner and outer aspects of the extremities with wide excision of edematous subcutaneous fat and aponeurosis. It is a measure which seems definitely to control the progress of elephantiasis. The best results are obtained in patients treated by two or three weeks' rest in bed with elevation and firm bandaging of the limb preliminary to operation. A large amount of skin, fat and aponeurosis must be removed in order to obtain the best results. When patients are up and about after operation it is necessary to bandage the limb for an indefinite period, and oftentimes permanently. Before operation there should be a definite understanding between the surgeon and the patient with regard to the fact that the operation is to be done for the purpose of controlling a disease which if left alone usually grows progressively worse; that a perfectly normal limb is not to be expected as a result of the operation, and that it will be necessary for bandages to be worn following the operation. Second operations in which portions of the hypertrophied skin are removed may be performed on patients in whom considerable deformity remains after the first operation, with expectation of further improvement.

1. Malignant Tumors of the Thyroid.—Louis B. Wilson presents an analysis of the literature and the data of 290 patients with malignant tumors of the thyroid who have been examined in the Mayo Clinic up to December 31, 1920, which he summarizes as follows: (1) Malignant tumors of the thyroid are much more fre-

quent than is generally believed. Their correct clinical diagnosis is frequently missed (a) because they may have periods of development of from five to fifteen years, and patients are not followed up long enough after operation, and (b) because not infrequently the tumor in the thyroid itself is relatively small and the character of the metastasis is not determined, owing to the rarity of necropsies. (2) Pathologic diagnosis is difficult owing to the great variation in the histology of the tumor tissue and its resemblance to that of non-malignant processes. (3) There has been a marked failure of American surgeons to report in the literature their cases of malignant tumors of the thyroid; this should be corrected. (4) Insufficient observations are at hand for determining the geographic incidence. (5) The age incidence at the date of diagnosis is greatest in the fifth decade. (6) The distribution by sex is about one man to two women. (7) Patients usually seek medical advice on the occasion of recent rapid growth in a long-standing nodular tumor of the thyroid. Some give histories of slow, continuous growth. (8) Early thorough operations give a fair percentage of cures. Palliative operations in late cases with extensive local involvement are warranted. (9) Pathologic diagnosis must take into account the usual development of malignant tumors of the thyroid from proliferating adenomas. (10) A series of photographs of specimens, gross and microscopic, of 35 illustrative cases is presented with brief clinical and pathological notes to serve as an atlas in assisting the pathologist in diagnosis. (11) The pathologist must be thoroughly familiar with the characteristics of proliferating adenomas, as first described by Langhans in all their stages. (12) The pathologist must be on the lookout for the possible relationship of bizarre metastatic growth of tumors of the thyroid. (13) The pathologist in his diagnosis for the guidance of the surgeon must consider the relative preponderance of proliferative and degenerative processes in the tumor, but a proliferating adenoma in a patient of cancer age should not be considered benign unless the process of degeneration is very extensive and thoroughly overbalances that of proliferation.

4. Results of Treatment of 115 Cases of Fracture of the Shaft of the Femur at the University of Pennsylvania Hospital.—Eldridge Lyon Eliason summarizes his observations on this series of cases as follows: (1) In patients under eight years of age the Bryant or perpendicular treatment gave the best figures, 85 per cent. excellent, or 100 per cent. good results. In this group all results were reported as good. (2) In the 88 cases 10 years of age or over, the primary reduction and dressing was not satisfactory in a single case. (3) A small group of eight cases later set in plaster under traction, all showed shortening or nonunion. (4) The next group of 20 cases dressed in the flexed position with weight traction gave 25 per cent. good results with no deformity. (5) In operative cases infection occurred in none of the drained wounds. Every case, however, showed slight infection around the Steinmann nail. (6) Internal fixation failed to hold the fracture in 21 of 54 cases. Causes of this failure were in a greater number of cases due to the position in which the limb was splinted, 20 being dressed in the flat position, and to a much less to infection, only three cases. (7) Nonunion, or better, union delayed longer than seven weeks was most often due to faulty fixation of the fracture, and occurred in 22.2 per cent. of the operative, 0.86 per cent. of the nonoperative, and 10+ per cent. of the entire series. It is hardly fair to include these figures as other than undetermined, as they have not been heard from finally. (8) Operation gave 81.6 per cent. good results; nonoperative methods gave 73.9 per cent. good results in the entire series of 115 cases. It must be remembered, however, that this last figure is helped enormously by including the 24 youngsters with 100 per cent. good results. (9) Of the operative procedures, the use of plates and screws with wound drainage and the limb dressed in plaster, in flexed position, with postoperative traction maintained, gave 90 per cent. perfect results plus 10 per cent. good. All other operative methods gave but 33 1/3 per cent. perfect results, plus 33 1/3 good results. Plaster casings are not a good permanent dressing unless traction is used and the case kept under close observation until union is firm and especial care taken that as shrinkage of the limb occurs, a new cast be applied. This last is very important for if there is too much room in the cast at the fracture site each time the patients raise themselves in bed the psoas muscle acting against the fracture will loosen the internal fixation. If these precautions are taken, however, plaster makes an excellent dressing if cut out so as to permit knee and ankle motion. (10) From the above facts it may be seen that the best treatment was operation with plate fixation and drainage and the same amount of attention given to external fixation, flexed position and traction as would be given were the case treated by the closed or nonoperative method.

1. Pituitrin in Obstetrics. A. M. Mendenhall.
2. Student Nurse Recruiting Movement. Annabelle Peterson
3. Cesarean Section for Hydrocephalus. Thomas J. Sullivan

1. Pituitrin in Obstetrics.—A. M. Mendenhall cites an impressive array of authority against the use of this drug, and examines the possible indications for its use. He says no one questions its safety and value under a great many conditions that may arise following the birth of the placenta. Two noted obstetricians are giving it routinely immediately upon the birth of the child; both have very large series of cases and as yet have had no unpleasant results, but until more has been done along this line definite conclusions had better be reserved. A number of operators are administering pituitrin just as the uterus is being incised in cesarean section, or very promptly after extraction of the child, and when sustained by ergot this procedure may be strongly indorsed. Some authorities report fairly successful results in the administration of pituitrin to aid in the emptying of the bladder during the puerperium. When the cervix is fully dilated, when it can be accurately determined that there is no disproportion between the passage and the passenger, when the presentation and position are normal, when there are no obstructing tumors, and when the pains are weak and declining we may be said to have indications justifying the cautious use of small doses of pituitrin—2 to 3 minims—remembering that episiotomy, or low forceps, or both, are usually better obstetrics. Contraindications to the use of this drug are undilated cervix; disproportion between passenger and passage; abnormal presentation or position; pressure of obstructing tumors; scar from previous cesarean section or myomectomy; heart disease in the mother; eclampsia; threatened asphyxia of the child *in utero*, and when contractions are already strong. If the above indications and contraindications are met it is obvious that the administration of pituitrin during labor at least will be exceedingly infrequent. In conclusion a warning is sounded that he who administers pituitrin to a patient in labor is using a very powerful and quick acting drug, whose strength is unknown and whose action upon the particular patient can by no means be predicted, whose use has resulted in the prompt death of a large number of women and a still larger number of children, and whose usefulness is limited to very narrow fields.

6. Instinct and Conflict. Ernest W. Jones.

1. The Successful Treatment of Leprosy.—Leonard Rogers reviews reports of the results of the treatment of leprosy with preparations of the fatty acids of chaulmoogra oil, and records further developments of his work along this line. A recent modification of practical importance is the intramuscular injection of ethyl ester compounds of the fatty acids of chaulmoogra oil, in place of the more troublesome intravenous injections of sodium salts, which allows of a larger number of patients being treated in the same

period of time. The fatty acids of linseed oil, cod-liver oil, soya bean oil, and Japanese sardine oil have also been tested. The preparation from soya bean oil proved to be very suitable for subcutaneous or intravenous injection, though it does not appear to be better than the former preparations from other oils. Satisfied that the gynocardate of soda, intravenously, could produce breaking up of the lepra bacilli in the tissues, the author thought of the possibility of obtaining a similar result in the still more important acid-fast bacilli of tuberculosis. Hesitating to use the new drug because of the danger of producing prolonged febrile reaction, he turned to the sodium salt of the fatty acids of cod-liver oil. He first used this preparation in leper patients whose veins no longer permitted the intravenous use of the more irritating gynocardate, and soon observed that patients, who had ceased to improve further on the latter drug, might once more progress, and eventually clear up completely, on sodium morrhuate. In tuberculosis it has been found that the treatment is at least harmless and the writer is hopeful that it will prove as useful as the tuberculin treatment and will be much safer in the hands of the profession at large. It would seem to promise better in chronic localized tuberculosis than in pulmonary tuberculosis.

Journal de Médecine de Paris.

August 30, 1921, xl, 24.

Lane's Disease.—Pauchet gives an extended account of chronic intestinal stasis. He relates that in 1900 he saw a case which was the first encountered by himself, long before he knew anything of Lane's account. It was an appendicitis in which the small intestine was adherent to the pelvis. He thought the adhesion of inflammatory origin, and omitted to divide it. The appendectomy failed to relieve, and there was a long period of invalidism, culminating in tuberculous peritonitis. In operating for the latter the intervention, including a short-circuiting of the intestine, he reached the conclusion that the iliac kink due to the pseudo-adhesion had been responsible for all the mischief. The appendectomy had been performed at the age of 13, the second laparotomy four years later, and at the age of 20 the young woman was in first-rate health. He had evidently cured a case of Lane's disease by major surgery and by accident. During the two-year period, 1904-6, he had done fifteen of these operations, and in the latter year reported the series to the French Congress of Surgery. He was at the time still ignorant of the writings of Lane, but soon after this time had read the latter. In 1908, now under the influence of the latter's teachings, he did an ileosigmoidostomy without benefit, but afterward performed total colectomy with remarkable restoration of health. Ever since 1904 he has made a study of Lane's kink in all abdominal operations, and in the French Congress of Surgery for 1912 he reported the results of 33 entero-anastomoses in which no less than seven distinct procedures were tried out. The total number of operations for Lane's disease performed by him in the past 18 years now runs into hundreds, and comprises colopexy, cololysis, coliplication, short circuits and colectomy, total and partial, etc., etc.

Arterial Tension in Pulmonary Tuberculosis.—Betchov and Farbarge-Vail reach the following conclusions. There is no definite specific hypotension in this affection. It is, in fact, absent in the pretuberculous and initial phases, and as long as the general condition is not much impaired; and develops during the advanced stages and cachexia. When present it is often limited to the systolic pressure. Hypotension has a certain prognostic significance within certain limits, but much less than that possessed by hypertension, which invariably means a good prognosis, despite the frequent coincidence of hemoptysis. Normal tension is also a good prognostic. Even frequent hemoptyses in hypertensive subjects do not prejudice the diagnosis. Low blood pressure has not the evil significance of high temperatures and normal temperature nor the good significance of hypertension. Pulse finds are more significant than pressure finds, tachycardia giving a decidely sombre prognosis. A pulse of normal frequence ranks with hypertension in the opinion of the writers as a favorable prognostic sign.

Observations on Pellagra.—Lustig and Franchetti, after an extensive survey of the more recent outbreaks of the disease in Italy come to the following conclusions. All the observations in the paper agree in pointing to alimentation as the source of the disease, with especial emphasis on diets with a maize basis. Whether the diet is intoxicant or merely defective, or both, is still a problem. If perfectly healthy maize is defective in some substance, then the attempt to sustain life with it must lead to a deficiency disease, and a hypothesis of a maize toxin is unnecessary. This view makes it intelligible that the disease could occur in the absence of maize from the diet, provided that the latter was defective in the same vitamine. Certain Turkish prisoners in Egyptian prisons during the war were properly fed but arrived in the prison in a notable state of denutrition. They brought no microorganism with them as far as bacteriological tests were made, yet developed pellagra. The only explanation was inability to assimilate vitamin-containing aliment. Such facts, and they are not unique, argue for the presence of an initial failure of digestion and assimilation, due perhaps to local enteric lesions of unknown nature. In similar cases of pellagra developing in prisoners, as in the Boer war, the diet was chiefly decorticated maize. Experience in the United States, while often accusing maize, has as often, perhaps, exculpated it as the fixed cause of the disease. The authors maintain that in Rumania the postbellum outcropping of the disease was brought in close connection with the use of maize unfit for consumption, as contrasted with the use of wholesome maize.

Brazil-Medico.

Cancer in Brazil.—Oscar Clark states that owing to the great frequency of this affection in civilized countries it would be of interest to determine its incidence in Brazil. As far as the author's experience goes the latter is relatively low. During the past ten years of the Medical Clinic of the University of Rio—the section known as the Second Dispensary—nearly 7000 cases of disease have been diagnosticated, and among this number there were but 40 cases of cancer. Of these 26 were seated somewhere in the digestive tube. The stomach was the seat in 16, colon in 4, and esophagus in 6. There were two cases of cancer of the larynx and one of the prostate. The remainder were in the abdominal cavity, and scattered as to location; while in several cases the exact diagnosis seems to have been in doubt and a few may have been sarcomata. It must be borne in mind that this material belongs to the internist only, which must account for the absence of cancer in the genitals, skin, etc. In a recently published graduation thesis on cancer in Brazil the total number of deaths from cancer per annum in Rio is given as 450. As this city has nearly a million population the cancer death rate is less than half that of the average European or North American city. São Paulo, with about 450,000 inhabitants, has 300 annual cancer deaths and thus a higher mortality. In Pernambuco, with over 200,000 people, the annual death loss is but 50—the rate being about a fourth of the usual urban mortality. The author is by no means sure that these figures indicate a lower incidence than what may be termed normal for cities. Brazil is unhealthy and many die off before the cancer age; diagnostic refinements and more autopsies might show additional cases. The work of the Radiographic Institute shows that external cancer is of very common occurrence, while, in the private clinic of de Mendonca, neoplasms of all kinds, including those internally situated, are numerous.

Book Reviews.

EPIDEMIC RESPIRATORY DISEASE.—The Pneumonias and Other Infections of the Respiratory Tract Accompanying Influenza and Measles. By EUGENE L. OPIE, M.D., Colonel, M.R.C., U. S. Army; Professor of Pathology, Washington University School of Medicine; FRANCIS G. BLAKE, M.D., Major, M.R.C., U.S. Army; Associate Member of the Rockefeller Institute for Medical Research; JAMES C. SMALL, M.D., formerly First Lieutenant, M.C., U.S. Army; Bacteriologist, Philadelphia General Hospital; and THOMAS M. RIVERS, M.D., formerly First Lieutenant, M.C., U.S. Army; Associate in Bacteriology, Johns Hopkins University. Containing 398 pages. Illustrated. Price, $6.50. St. Louis: C. V. Mosby Company, 1921.

DOCTORS Opie, Blake, Small and Rivers present their combined army experiences with epidemic respiratory diseases with reference especially to lobar pneumonia, bronchial pneumonia and influenza. The study is presented in various chapters beginning first with the etiology of influenza, introducing next the clinical features and bacteriology of influenza and its associated purulent bronchitis pneumonia. This is followed by a study of secondary infection in the war treatment of influenza and pneumonia in which secondary infection with streptococcus hemolyticus is discussed; secondary infection with pneumococcus in pneumonia; secondary infection in influenza; and methods for the prevention of secondary contact infection in influenza and pneumonia.

The next chapter deals with the pathology and bacteriology of pneumonia following influenza. Then a discussion is presented of secondary infection in the war treatment of measles and experience gained for the most part at Camp Pike. The bronchial changes, lobar pneumonia, suppurative pneumonia and pneumonia associated with acute infectious diseases other than influenza and measles are next studied from the viewpoint of their pathology and bacteriology.

From the collected studies certain conclusions are reached that were not wholly representative of the sentiments prevailing among pathologists and bacteriologists during the height of the epidemic. Thus these investigators point out that there is "no reason for believing that the influenza which prevailed in this country differed in any essential feature from that of previous epidemics and particularly of the pandemic of 1889 to 1890. Our studies have shown that an organism with the morphological and cultural characteristics of *B. influenzæ* of Pfeiffer has been constantly found in association with the disease, and so frequently demonstrated in association with its pulmonary complications that there is little doubt of its constant presence." This would seem to be contrary to the inference reached by MacCallum, in his textbook on pathology, who fails to subscribe to the thought that the Pfeiffer bacillus is the cause of this disease. The investigators point out further that while the sputum contains *B. influenzæ* in all instances, this organism has been constantly associated with other microorganisms, namely, pneumococci, *S. hemolyticus, S. viridans, M. catarrhalis* and others.

Empyema was found to be almost invariably associated with suppurative pneumonia caused by hemolytic streptococci.

B. influenzæ was found constantly with influenza when cultures and animal inoculations were made from various parts of the respiratory tract within from one to five days after the onset of the disease at a time when acute symptoms were present. Difficult identification in the presence of other microorganisms may have been conducive to overlooking this organism when only a single culture was made. *B. influenzæ* was found to be frequently an inhabitant of the mouth and throat of normal individuals. Inoculated monkeys, with the organism obtained from the nasopharynx of individuals suffering from influenza, were found to give symptoms of no clear definition, though the newly introduced organism thrived in the throat of the animals. The experiences at Camp Funston and Camp Pike, in which pneumonia following measles was responsible for the considerable number of deaths occurring in the United States Army during the period of the war, were studied with the finding that influenza attacking patients with measles had a part in the production of the pneumonia; though it is elsewhere recorded in the summary of investigation by these authors that influenza bacillus alone showed no evidence of being capable of producing pneumonia.

The findings throughout are accompanied by autopsy protocols and by such illustrations as are necessary to portray the typical gross and histological changes discussed in the text.

DIAGNOSTISCHE UND THERAPEUTISCHE IRRTÜMER UND DEREN VERHÜTUNG. CHIRURGIE Zweites Heft., Chirurgie der Wirbelsäule, des Rückenmarks, der Bauchdecken und des Beckens. Von Geh. Med.—Rat. Prof. Dr. G. LEDDERHOSE. Price, 45 marks. Leipzig: George Thieme, 1921.

THIS volume comprises four sections devoted respectively to the subjects in the title. There are thirty-two separate chapters. In the great majority of these chapters diagnostic and therapeutic blunders are separately discussed under each title. In a few there are no therapeutic errors enumerated. The chapter on the umbilicus is much more voluminous than the average and comprises numerous subtitles. Since there are but 150 pages of text the average number of pages per chapter is less than five, which prevents much teaching by case histories. It would seem that with so interesting and important a subject as diagnostic and therapeutic errors it would be worth while to produce a much larger volume and cite numerous case histories, as in Cabot's "Differential Diagnosis" and similar works.

THE JOHNS HOPKINS HOSPITAL REPORTS. Volume XX, Fasciculus I. The Pathology of the Pneumonia in the United States Army Camps During the Winter of 1917-18. Volume XX, Fasciculus II. Pathological Anatomy of Pneumonia Associated with Influenza. By WILLIAM G. MACCALLUM, M.D., Baltimore: The Johns Hopkins Press, 1920 and 1921.

FASCICULUS I of this volume is apparently a reprint of the article which formed Monograph No. 10, issued by the Rockefeller Institute. It has been previously noted in these columns.

In Fasciculus II the former study has been somewhat extended and a number of new cases have been added. The author has found no reason to alter any of the conclusions which he expressed in the first article. He is convinced that the typical forms of pneumonia differ in their pathological anatomy depending upon the bacterial cause of the disease and is able to recognize streptococcus hemolyticus, influenza bacillus, staphylococcus and pneumococcus pneumonias by their lesions at least in typial instances. He holds to the rather general impression that epidemic influenza is caused by an as yet unrecognized organism, possibly related to those which cause the exanthemata. The cases have been very carefully and completely studied and the material is clearly presented.

A MANUAL OF PHYSICS, THEORETICAL AND PRACTICAL, FOR MEDICAL STUDENTS. By HUGH C. H. CANDY, B. A., B.Sc. Lond., F.I.C., Lecturer on Chemistry at the London Hospital Medical College, and Arnott, Professor of Natural Philosophy in Queen's College, London. Second edition, enlarged. With a color frontispiece and 280 figures in the text. Price, $2.75. New York: Paul B. Hoeber, 1920.

THIS work is written to meet the requirements of the first examination in physics and chemistry which English medical students have to meet. It is divided into six parts, dealing with general physics, heat, sound, light, electricity and magnetism and practical physics. The various subjects are handled clearly and adequately; and at the end of each chapter there are some examination questions which serve the double purpose of enabling the student to see if he has mastered the contents of that chapter, and of showing the nature of the test to which he will be submitted at the hands of his examiners. The volume is of very convenient size, is well printed and illustrated, and should prove serviceable to students in their pre-medical course, as well as to others.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Thirty-third Annual Meeting, Held in Swampscott, Mass., June 2, 3 and 4, 1921.

THE PRESIDENT, DR. JOHN HOWLAND OF BALTIMORE, IN THE CHAIR.

(*Concluded from page 570.*)

The Rôle of the Fat Soluble Vitamine in Rickets.—Dr. ALFRED F. HESS of New York made this presentation which was illustrated by lantern slides. He said that, as was well known, there were two main theories of the etiology of rickets, the hygienic and the dietetic. So far as he knew there had been no investigation of the hygienic theory. It had not been thought to be possible to investigate it. It had seemed to him that there was a way of approaching this, so during the winter they had fed a number of infants on dried milk prepared in the summer, and instead of using the milk from the pastures in the summer they had used dried winter milk. It had been found that if the cow was on a ration that contained little grass the milk was almost vitamine-free. Twelve children were fed on the summer milk in the winter and 8 children were fed on the winter milk in the summer. The same percentage of children developed rickets in both groups, so that apparently diet did not seem to make any difference. In order to continue the study, Dr. Hess made use of the ultra-violet ray and followed the course of the rickets with the *x*-ray. The cases treated with the ultra-violet light were very quickly cured as shown by the calcification of the epiphyses and this occurred in the winter time. In March and April they tried sunlight, exposing the children gradually to the sunlight and in a few weeks calcification began. Some of these children were getting dried milk, some protein milk and some condensed milk, and they had been on these diets at least six months. Active rickets reached its highest incidence in January and its minimum in July. The healing of rickets was lowest in January and reached its height in August or September. Rickets was most marked in the winter or spring and least marked in the summer time. The ultra-violet light was given three times a week for three months, the time being gradually increased until the exposures were for twenty minutes at a distance of 125 centimeters. The *x*-ray pictures showed the progress made in calcification of the epiphyses during this treatment. These observations seemed to point to the fact that there was a hygienic factor in the etiology of rickets and that the question of sunlight was of dominant importance. Someone might say that exercise as well as light played a rôle but these children did not exercise more after they were subjected to the sunlight and ultra-violet light treatment than before. The moral was evident; it pointed to the value of sunlight in the prevention of rickets and, furthermore, it showed the importance of sunlight in child-caring institutions and hospitals.

Dr. ROWLAND G. FREEMAN of New York said it had always seemed to him that all we knew about rickets pointed to the fact that it was a disease caused by darkness. Children got rickets in the winter and not in the summer. About all the rickets we saw occurred in races used to a tropical climate. There were some very striking instances. In one Italian family coming under his observation there were six children, three born in Italy and three in this country. Those born in Italy were apparently normal while those born in this country had marked rickets. He did not believe it was going to be possible to say that rickets was a food disease when we saw such remarkable examples associated with bad hygiene and change in climate.

Dr. E. C. FLEISCHNER of San Francisco said he had come to feel that the outside environment was a factor in the etiology of rickets and that the greater amount of sunlight and the outside environment explained in part at least why there was less rickets in California than in the East. Dr. Fleischner asked Dr. DeBuys with reference to the incidence of rickets among the colored children in the South.

Dr. L. R. DEBUYS of New Orleans replied that rickets in New Orleans was very frequent among the colored children, more frequent than among the white. Speaking offhand, he thought it was just as frequent in the rural districts as in the city. The negroes in the rural districts lived in about the same conditions as those in the city as regards overcrowding and diet.

Dr. HENRY HEIMAN of New York called attention to the fact that in their investigations of rickets they had considered only the osseous system, and no stress had been put on the other systems which were undoubtedly affected. He felt that there was an individual and a predisposing factor. He felt that rickets should be considered as involving the ligametous, muscular and nervous systems as well as the osseous.

Dr. ALFRED F. HESS of New York said that he did not mean to state that diet did not play a rôle in the etiology of rickets or that rickets was not a dietetic disease and could not be brought about by poor diet. When on the same milk 25 per cent. of the children would get rickets and the rest would not, which showed that there was some individual idiosyncrasy. The point he wished to bring out was not so much the incidence of rickets as its cure by the ultra-violet light and sunlight.

A Clinical and Roentgenological Study of Enlarged Thymus in Infants.—Drs. KENNETH D. BLACKFAN and KARL F. LITTLE of Cincinnati presented this study, which was illustrated by lantern slides. It consisted of a clinical and roentgenological examination of the thymus both in normal infants and those who had presented thymic symptoms. An extensive series of radiograms taken before and after *x*-ray treatment had been analyzed with reference to the diagnosis of enlarged thymus. The results indicated that an area of dullness in the region of the thymus, with a corresponding shadow in the roentgenogram, occurred in a relatively large number of normal infants. That this was due to the thymus was shown by the fact that the shadow became smaller after exposure to the *x*-rays. A thymus large enough to be demonstrated by percussion and to show in the plate did not necessarily cause symptoms. The observation of previous workers that an enlargement of the thymus could be demonstrated by percussion and by roentgenograms was confirmed.

Dr. OSCAR M. SCHLOSS of New York stated that they had been collecting data on this subject. One hundred infants were taken at or immediately after birth and *x*-rays were made of their chests, and pictures were then taken monthly. In 70 of the 100 newborn infants there was a distinct upper mediastinal shadow. Fifty babies were followed throughout the year, and at the last examination 25 still showed a large upper mediastinal shadow. In none of the infants were there any symptoms that could with accuracy be attributed to the upper mediastinal shadow which was due in part at least to the thymus. In regard to percussion, they felt that when they found a distinct dullness they could be reasonably certain of an upper mediastinal shadow, though there were exceptions to this. In a few cases in which there was no dullness there was a large shadow. They were not satisfied with the results in this series and were running another series. During the course of the study they had verified the observation of Dr. Gerstenberger that the thymic shadow varied with inspiration and expiration. At postmortem they had checked up their technique in a number of instances to be sure that the shadow they had obtained was an enlarged thymus. When the postmortem showed a small thymus they never got a large shadow except in one case in which the thymus was fairly large and the *x*-ray had shown nothing.

Dr. ALFRED FRIEDLANDER of Cincinnati called attention to the fact that the *x*-ray gave no idea of the anteroposterior dimensions of the thymus. One might have a large flat thymus that gave no symptoms though it gave a large shadow, whereas a thymus might be thick anteroposteriorly and produce symptoms and yet give a small shadow. The mere fact of a large upper mediastinal shadow associated with enlargement of the thymus did not necessarily mean that symptoms were produced. It might be that as many as 46 per

cent. of children would be found to show an enlargement of the thymus and a large percentage of these showed no symptoms. If symptoms of thymic asthma were present, even though the *x*-ray showed no shadow, radiation should still be given. In a study of 300 cases they had found it worth while to employ radiation. Dr. Friedlander said he was in accord with the previous speakers that what an enlarged thymus meant was still to be determined.

Dr. MAYNARD LADD of Boston cited the case of a child with a negative history who was seized with convulsions, high fever, and cyanosis, and died suddenly. At postmortem the thymus was found to weigh 62 grams. It was difficult to understand how a gland of that size could exist without causing symptoms. It seemed that the symptoms might be due to an internal secretion rather than to pressure.

Dr. CHARLES GILMORE KERLEY of New York cited a case in which there were typical classical asthmatic attacks which he diagnosed as being due to enlargement of the thymus. The *x*-ray showed no evidence of enlarged thymus. The child was given four *x*-ray treatments and had had no attacks since.

Dr. JOSEPH BRENNEMANN of Chicago cited a case in which the *x*-ray showed a broad shadow, so broad that it approached the heart and yet there were no symptoms. If the child had had symptoms they would have been attributed to the thymus. It was important that more than one *x*-ray picture be taken. He had seen instances in which the thymus was apparently enlarged and when a second picture was taken it was not so apparent, due to the fact that one picture was taken at the end of inspiration and the other at the end of expiration. There was an idea that symptoms were aggravated for some hours after *x*-ray treatment. He would like to know whether others had found this to be true, and if it was true whether it should lead one not to give the *x*-ray treatments at a time when there was more or less aggravation of symptoms.

Dr. FRITZ B. TALBOT related that a short time ago his resident, Dr. Parsons, was making a study of rabbits. One of the rabbits died suddenly, and the postmortem showed an enlargement of the thymus. This was the first time at the Massachusetts General Hospital that a rabbit was found with an enlarged thymus.

Dr. LANGLEY PORTER of San Francisco said that he had noticed a thymus might be enlarged and yet produce no symptoms. At the Stanford Hospital they had had a Mongolian idiot who died at about four years of age of pneumonia. He had never shown symptoms of thymic asthma, but at autopsy a thymus was removed which weighed over 55 grams.

Dr. HENRY HEIMAN of New York said that thymic asthma was a very rare disease. Cases of real thymic asthma were not hospital cases and the deaths occurred at home. Thymic asthma must not be confused with laryngismus stridulus, diphtheritic infection, and those cases in which death occurring suddenly one found a deformity of the glottis and epiglottis. Again thymic asthma must not be confused with latent spasmophilia.

Dr. ROWLAND G. FREEMAN of New York thought that thymic asthma was sometimes taken to be simply convulsions such as occurred with slight infections. In some of these cases the convulsions ceased after treatment with the *x*-ray. He cited a case of thymic asthma in which the symptoms were relieved by *x*-ray treatment though the shadow on the *x*-ray plate was apparently larger than before the treatment. He had had two other cases treated without reduction in the size of the thymus. Dr. Gerstenberger's sign was very valuable. If one was dealing with a tumor in the upper mediastinum that got larger and smaller with inspiration and expiration he might be pretty sure it was the thymus and nothing else.

Abdominal Pain and Throat Infection.—Dr. JOSEPH BRENNEMANN of Chicago read this paper, in which he directed attention to a symptom which in his experience and that of his associates was of very frequent occurrence and, so far as he knew, had received little or no mention in the literature. This symptom was that of abdominal pain occurring often to the exclusion of all other subjective symptoms in the course of throat infections in children, including the whole series of upper respiratory infections. The nature and location of this pain were fairly constant; the degree and time of occurrence varied much in different individuals. It might occur early or late and often persisted throughout the illness, sometimes lasting for weeks and even months after all other symptoms had disappeared. The child quite regularly indicated that the region of the umbilicus was the site of the pain. In seeking the cause of this pain one must direct his attention to the mesenteric and retroperitoneal glands. Several cases were cited in which operation was performed in the presence of a severe pain of this kind and such enlarged mesenteric and retroperitoneal glands were found. Two routes of infection were of course possible, by blood stream and by direct transmission. The former seemed improbable, for a marked general adenopathy was not especially characteristic of these infections. The true cause of the pain might be, at least in part, a localized enteritis or colitis, rather than lymphadenitis itself, and possibly some specific or selective localization might account for the fairly constant pain in the umbilical region. That the glands might, however, become involved secondarily, even to the point of abscess formation or might continue to be enlarged for a time after the intestinal lesion was healed, was probable enough and exactly analogous to what happened in secondary adenitis of the cervical and retropharyngeal lymph glands following a throat or postnasal infection. This might explain the recurrent pain in the abdomen. It was of practical value to know that there was such pain and to be familiar with its clinical setting; but one must not allow this type of pain to cause him to overlook appendicitis.

Severe Infantile Malnutrition—The Energy Metabolism with the Report of a New Series of Cases.—Dr. FRITZ B. TALBOT of Boston said that in this series the children were all underweight and represented malnutrition due to a variety of causes. A table giving a comparison of the heat production of infants of like body weight and height but of different ages, showed a higher metabolism for older infants than for younger infants of the same size. This was significant because the older infants had a greater degree of malnutrition than the younger infants with which they were compared. A chart also showed what had been recognized for some time, namely that the heat production per kilogram of body weight was higher in the malnourished or marasmic infant than in the normal infant. Children with the greatest degree of malnutrition had apparently the most abnormal metabolism. This was rather difficult to account for but allowed of two explanations: (1) Because of the malnutrition there was a diminished amount of active protoplasmic tissue to make heat, or (2) there was a normal amount of protoplasmic tissue but because of malnutrition or some concomitant factor the heat-forming tissues were incapable of making the same amount of heat as during health. The composition of the body showed little or no difference between the percentage of nitrogen in well-nourished fat infants, thin infants, or markedly malnourished infants, and it might be assumed that the proportion of protein tissue in malnutrition was not abnormal. Before this could be accepted, however, further investigation was necessary. The second possibility conformed with clinical experience and might be taken as the more plausible explanation. It was conceivable that when the metabolism became so depressed that the normal temperature could not be maintained except by the external application of heat, these infants had entered into the same category as cold-blooded animals, the level of whose metabolism was determined in general by the surrounding temperature. There was no appreciable change in the metabolism of children with severe malnutrition until there was a loss of 20 per cent. in the body weight. Beyond this point there was presumably a loss of subcutaneous fat and a relative increase of body surface. With the increasing malnutrition the divergence from the normal became greater and body heat was lost more easily because of the lack of the insulating layer of subcutaneous fat and of the greater radiation of heat due to the relative increase in body surface as compared to the weight.

Dr. THOMAS S. SOUTHWORTH of New York said Dr. Talbot had given a very valuable demonstration. In looking over some old reports he came across the work of an investigator which showed that an atrophic in-

fant used two ounces more milk if its head was exposed. From this it was deduced that smaller children wearing a cap in the cooler weather conserved the body heat. The same thing was applicable to older children. In thin and anemic children the nutrition could be helped markedly by using flannels as the extra protection favored the nutritional and metabolic processes. Fashion was very irrational when it decreed that children should go with their legs exposed in cool weather.

A Febrile Exanthem Occurring in Childhood.—Drs. BORDEN S. VEEDER and T. C. HEMPLEMANN of St. Louis presented this contribution in which they described conditions met with in a group of cases characterized by high fever lasting three or four days, followed by the development of an eruption coincident with the fall of fever. The eruption faded within twenty-four to forty-eight hours. During the febrile period there was an entire absence of all physical signs or symptoms. There was no coryza, tonsillitis, cough, bronchitis, lymphatic enlargement, splenic enlargement, diarrhea, or constipation. The most striking thing was the complete absence of symptoms accompanying the high fever. One patiently waited for the development of a concealed pneumonia or some such cause of an obscure fever, when suddenly the rash appeared and the temperature dropped. They had seen in all twenty of these cases during the past winter: in eight of these a blood count had been made, and the only striking sign they had noted was a distinct leucopenia with relative lymphocytosis. The blood count was the only diagnostic clue. The leucopenia dropped as low as 3,200 cells in two cases. In all but one of the eight cases there was a relative lymphocytosis present, amounting to from 80 to 90 per cent. With the exception of a relative increase in lymphocytes and a relative decrease in the polymorphonuclears, the other cells stood in normal relation to each other. Most of the cases occurred in the second year. In none of the reported cases nor in any of the other cases observed had a second case been seen in the same family. The disease, therefore, seemingly did not belong to the ordinary group of exanthemata in childhood transmitted by direct contact. The eruption was morbilliform and consisted of small red macules of maculopapules from 1/16 to 3/16 of an inch in diameter. They pressed out easily, similar to a rose spot. The lesions were usually profuse and fairly well-distributed over the body, lower part of the face, neck, and extremities. It was their belief that the symptom complex was a specific entity which was not described in the textbooks. Dr. Zahorsky had described this symptom complex, in 1910, as "roseola infantilis" and again, in 1913, as "roseola infantum." His description agreed with the picture they had been observing. They did not consider that roseola infantum was the proper name to apply to this symptom complex as it formerly pertained to a large indefinite group.

Dr. ROWLAND G. FREEMAN of New York said he thought they all had seen such cases. They were very common. The children ran an elevated temperature for three or four days and after the fall in temperature they developed a rash. He would not be sure they did not have catarrhal symptoms.

Dr. THOMAS B. COOLEY of Detroit said they had had the identical thing in Detroit. The blood picture was the same and the exanthem the same. It had occurred at a time when there was an outbreak of paratyphoid B fever from which it was extremely difficult to differentiate it.

Dr. JOHN RUHRÄH of Baltimore said he had seen sixteen cases of this entity, but would reserve his description for some other time.

Dr. HENRY F. HELMHOLZ of Rochester, Minn., said they had had a small epidemic of this entity. The cases he had seen corresponded with Dr. Veeder's description. In a group of three cases in one family the eruption was of the urticarial type and the symptoms more severe. The urticaria subsided only after the administration of adrenalin.

Dr. HENRY HEIMAN of New York said he supposed all had seen such cases and the clinical diagnosis was usually intestinal toxemia accompanied by urticaria or erythema. It would be interesting to study the milk supply.

Dr. JOSEPH BRENNEMANN of Chicago asked whether Dr. Veeder had any drug which he used as a routine, such as aspirin.

Dr. VEEDER of St. Louis said that none of these children were receiving any drugs. He had eliminated the possibility of a drug rash. There were no toxic symptoms. These children came from all sections of the city and mostly from the better classes. They were not getting milk from the same dairy.

Indications for the Removal of the Spleen in Infants and Children.—Dr. FREDERIC H. BARTLETT of New York reviewed the most recent studies of the function of the spleen and cited the reported splenectomies in children under twelve years of age and their subsequent histories. He said that hemolytic jaundice, Gaucher's disease, Banti's disease, and von Jaksch's anemia were four names given to pathological processes for the relief and cure of which removal of the spleen might be the only treatment. Banti's disease and Gaucher's disease had no distinguishing symptoms and physical signs by which they could be clearly diagnosed in their early stages, and it was just in the early stages that splenectomy was of the greatest value. Von Jaksch's disease was still *sub judice*, being regarded by some as not a distinct entity. In view of the difficulty of giving a name to certain symptom complexes in which anemia and a large spleen were the prominent manifestations, and for which splenectomy might be the only proper treatment, it was necessary to have certain criteria for the removal of the spleen. These criteria were brought out in the analysis of three cases reported in the paper, two cases of Banti's disease and one of Gaucher's disease, all treated by splenectomy. In the 41 cases collected from the literature no instance of leucemia appeared. This disease above all others must be excluded in a decision to remove the spleen. Removal of the spleen was contraindicted in leucemia. The first case presented the anomalous situation of a spleen which recorded the changes belonging to Banti's disease and the blood picture belonging to von Jaksch's disease. If the two diseases were distinct, the logic of the situation forced one to accept the proposition that the causative agent of von Jaksch's disease had elaborated its effect on the hemopoietic system; the causative effect of Banti's disease had elaborated its effect in the spleen. Emphasis was laid on the statement that a distinctly enlarged spleen might be a part of a pathological condition the relief or cure of which depended upon the removal of the organ; and secondly, that such an enlargement might be present in the first year of life. A study of the charts of repeated blood examinations in the two cases of Banti's disease showed in each instance a diminution in the number of erythrocytes, a hemoglobin percentage below normal, and leucopenia. The erythrocytes showed poikilocytosis, polychromatophilia, and marked pallor. These blood findings defined secondary anemia, which was characteristic of Banti's disease. The combination of a persistent blood destruction and of an enlarged spleen in spite of repeated transfusions and failure of radium to reduce the size of the spleen, furnished a good starting point for serious consideration of splenectomy. It was desirable, however, that a thorough search for evidence of blood regeneration as well as of blood destruction be made when one was confronted with the problem of splenectomy. Studies of the blood after splenectomy furnished a good index of the degree of improvement in the condition for the relief or cure of which the spleen was removed.

The Diagnosis of Tuberculosis in Childhood.—Dr. CHARLES HENDEE SMITH of New York said there was a widespread misconception in the minds of the medical profession concerning the prevalence of tuberculosis in childhood, the methods by which the diagnosis must be made, and the significance of the skin reaction. Tuberculosis was not a universal disease in childhood, in this country at least. The universal findings in Europe did not hold in America. The diagnosis of the presence of tuberculous infection rested largely upon the skin reaction which did not determine whether any given lesion was tuberculous, but did tell whether a child had been infected or not. The technique of the various skin tests was important. The value of the reaction was commonly lost by careless methods. The activity of tuberculosis must be judged by the

temperature curve and by the other signs of toxemia (malnutrition, anemia, etc.) The site of the lesion was often difficult to find. The bronchial nodes were most commonly involved, yet gave out few signs. D'Espine's sign was the best of these; its value was not widely appreciated. The manner in which it was elicited and recorded had not been standardized. The present report was concerned with an analysis of 550 cases with reference to this sign. The *x*-ray should show tracheobronchial enlargement, but was often disappointing. D'Espine's sign below the third, and especially below the fourth, dorsal vertebra was very suggestive of tuberculosis.

Dr. FRITZ B. TALBOT of Boston asked Dr. Smith whether he had any records in this group as to whether the children had had whooping cough. He had made a series of observations during and after whooping cough which showed marked enlargement of the bronchial lymph nodes by the *x*-ray.

Dr. JOSEPH BRENNEMANN of Chicago called attention to one precaution that should be taken when one got a series of negative von Pirquet reactions, where before he had been getting positive reactions. When that happened one should make control tests with a different tuberculin.

Dr. W. PALMER LUCAS mentioned that another condition might also give the D'Espine sign, namely, a low grade influenzal infection. In quite a series of cases of that kind they had found the same picture Dr. Smith had described, namely, the D'Espine sign positive below the fourth and extending down to the seventh or eighth dorsal vertebra; in these cases the von Pirquet was negative yet there was a positive clinical picture.

Dr. LANGLEY PORTER of San Francisco said he believed D'Espine's sign was a very valuable and much neglected addition to our clinical methods. He had never found D'Espine's sign below the fifth and rarely below the fourth dorsal vertebra where there was not some definite change. The position of the patient was important in determining the point at which the sign was heard. Dr. Smith said he made the examination with the patient in the erect position. The speaker seated his patients with the back flexed and the head bent forward; then he usually heard the sign at about the fifth dorsal vertebra. It would be an advantage to have a standard position.

Dr. J. CLAXTON GIDDINGS of Philadelphia said the number of positive von Pirquet reactions was high. He felt that the von Pirquet reaction represented the number of infections, but he felt strongly that the clinical fact that we saw so little tuberculosis between the ages of four and fourteen probably depended upon the dose of infection and the resistance of the subject. He believed that many cases of malnutrition and undernutrition were dependent upon neoplasms in the glands that could not be definitely proven.

Dr. SAMUEL MCC. HAMILL of Philadelphia referred to a series of cases in which he had applied the Calmette, the Moro, and the von Pirquet tests, which indicated that the von Pirquet test had the same measure of accuracy as the Calmette, and also that the Calmette test was a failure as an indication of the incidence of tuberculosis. Dr. Hamil emphasized the importance of careful technique in the application of the von Pirquet test.

Dr. CHARLES HENDEE SMITH stated that whooping cough, influenza, or any affection that gave an inflammatory reaction in the lung, might give D'Espine's sign. One must rule out other lung conditions before making a diagnosis on the D'Espine's sign. The tuberculin used in making the tests should be tested out frequently on known cases. A great deal of value should be attached to percussion and it often gave positive findings, but it was not easy to teach a young man to percuss lightly and to elicit the more delicate signs, while it was comparatively easy to learn to elicit D'Espine's sign.

Certain Aspects of School Medical Inspection.—Dr. FRANK SPOONER CHURCHILL of Milton, Mass., presented this contribution, in which he said he had just completed two years' work as medical director of the public schools in a suburban town in Massachusetts with a total population of 9,000 and a school population of approximately 1,600. For this work there were available at first only two physicians, one school nurse, the grade teachers, two teachers of physical training, and certain community organizations. The work of general examination had been divided between teachers, school nurses, and school physicians. Weighing and measuring and the testing of sight and hearing had been done by the grade teachers; the examination of the head, scalp, teeth, spine, posture, and feet, by the school nurse. After that the school physicians, Dr. Augusta Williams for the girls and the writer for the boys, had examined nose, throat, teeth, glands, heart, lungs, spine, and feet. All data of each pupil were recorded on a tabular card of such size and arrangement that one card would suffice for the examinations made year by year. In addition to the complete examinations all the pupils in the grade schools were weighed once a month, the records being kept for inspection by the children themselves. Provision was made for the correction of defects. The chief interest in this work centered in the nutrition of the pupils and in certain local anatomical defects. The total number of children examined was 1,552 in 1919, of which 39 per cent. were under weight, and 16 per cent. were 10 per cent. or more under weight; in 1920, 1,569 were examined and 56 per cent. found under weight; and 23 per cent. were 10 per cent. or more under weight. The explanation offered for this increase in underweight was that about one-fifth of the children of this community entered school handicapped by a severe state of malnutrition. The effect of school life upon the malnutrition appeared to be *nil*, but in the school course there was an increase in numbers showing malnutrition, and this took place in the storm and stress period of early puberty, subsiding with the complete establishment of puberty. The report on anatomical defects confirmed well known figures. There was a satisfactory absence of tuberculosis.

Respiratory Infections in School Children.—Dr. RICHARD M. SMITH of Boston presented this paper, in which he stated that the present study was undertaken in the hope that some suggestions might result as to a more definite means of combating respiratory infections. No definite line of attack could be suggested from the evidence at hand. It had demonstrated clearly several things, the most striking of which was our lack of real knowledge with reference to these infections and the necessity for further study. The figures in this connection were taken from Mr. River's Open Air School for Boys in Brookline. During the years 1917 to 1921, out of a possible 100 per cent. attendance, illness caused absence of 11.62 per cent. in 1917-1918; 9.76 per cent. in 1918-1919; and 12.77 per cent. in 1919-1920. This was two or three times the percentage of absences not connected with illness. Of the absences due to illness, respiratory infections caused about 54 per cent.; contagious diseases and quarantine, 24 per cent. Respiratory infections were twice as great as those from contagious diseases except in one instance when a mumps epidemic made a large number of absences from contagious disease. A detailed study was made of the respiratory infections during the period of greatest prevalence to determine, so far as possible, the facts with reference to the distribution of the infections. From these facts an attempt was made to detect any possible channels of infection in the school. Respiratory infections were most numerous during the months of January, February, and March. In general they were a little more prevalent and of longer duration in the lower grades. Other schools also showed greater prevalence of illness in these grades. A study was made of all pupils absent because of respiratory infections during the month of January to determine, if possible, any connection between their proximity in the schoolroom during rest periods, at meals, during classes, or during transportation. Definite contact infection could not be proved. It was striking, however, that the distribution of respiratory infections at any one time was in general among boys who were near together, particularly those who were near together at rest period or in music. This would seem to indicate the desirability of particular precautions during times of close contact or when using the voice.

The Management of a Diphtheria Outbreak in a Private School.—Dr. E. C. FLEISCHNER stated that Schick had placed diphtheria from the hygienic standpoint upon an entirely new basis. Formerly in some places

an outbreak of diphtheria was handled by sending the students home and leaving them to the very uncertain management of the family doctor. In others more properly supervised cultures were taken in the school, carriers sent home with instructions as to isolation and prophylactic doses of antitoxin, given either in school or by a medical adviser at home. The school was invariably closed for a considerable period of time and often numerous fantastic procedures employed to disinfect rooms or correct errors in plumbing hoping thereby to prevent a recurrence of the disease by methods absolutely futile. An outbreak of three cases of diphtheria in a boarding school having 150 students was promptly and successfully controlled without disorganization of the school, though there was a certain human element bound up in a problem of this kind that taxed the ingenuity and patience of those who had it in charge. An interesting fact learned from the records of this outbreak was that the percentage of positive Schick tests was 65. It suggested the possibility, considering that these boys came from a stratum of society where diphtheria was not prevalent, that repeated exposures to the disease played a rôle in the development of a natural active immunity. In summarizing Dr. Fleischner emphasized the following facts as a means of controlling a diphtheria outbreak in a boarding school: (1) Immediate isolation and treatment of the sick children. (2) Immediate, carefully supervised nose and throat cultures on all members of the school. In the taking of cultures the swabs should be introduced far back into the posterior portion of the nares, and from the crypts of the tonsils, if the tonsils were present, and when removed the cultures should be taken from the tonsillar fossæ and as high up on the posterior pharyngeal wall as possible. (3) Schick tests with proper controls on all members of the school within twenty-four hours. (4) Administration of 1,000 units of antitoxin subcutaneously to all children having positive Schick reaction at the end of forty-eight hours. (5) Reculture of smears from noses and throats and all contacts two days after the primary culture. (6) Any ill child should be isolated from the healthy children and from true diphtheritics until a positive diagnosis was established. (7) All of the carriers should be immediately isolated and where it was possible, toxicity tests should be employed to avoid the exposure of those children having virulent diphtheroids to those with true virulent organisms. (8) When the outbreak was controlled, active immunity should be conferred upon all children with positive Schick reactions by the proper injection of toxin-antitoxin mixtures.

Left Handedness as an Educational Problem.—Dr. A. Caillé of New York presented this paper, in which he stated that left-handedness could be traced back to antiquity and that we had Biblical evidence of the efficiency of the left-handed. The study of the problem of sinistrality naturally led up to the question: "What can be done to bring about a more adequate adjustment of a left-handed child to a right-handed environment or, as Beeley expressed it: "If left-handedness was hereditary to what extent was it expedient to force a sinistral to become right handed?" In view of the probability that left-handedness had a structural atavistic basis and was not merely an acquired faulty habit, the disciplinary attitude of parent and teacher toward left-handedness should be adjusted to the degree and character of its manifestations. *Mild Types* in which the stimulus for preferential action was weak were readily overcome by educational efforts. Also it was not difficult to train the left hand when the use of the right hand was lost through injury or disease. *Mirror writing* with sinistrality could be overcome in some instances by giving simple exercises which would make the child appreciate the discrepancy between his reproduction and the copy. Results would depend upon the degree of anatomical disturbance. In persistent sinistrality, particularly when combined with speech defects, right-handedness should be encouraged but never forced. Unreasonable discipline created an unbalanced condition akin to mental chaos. One might with more confidence rely more upon an internal or self-imposed discipline which inevitably came sooner or later, even though the preferential instinct might remain to a certain extent throughout life. According to G. D. Robbins, Director of the Boston Stammerers' Institute, sinistrals with speech defects might overcome cerebral congestion and encourage normal speech by slow and moderately deep breathing exercises. The correction of eye strain and of nasopharyngeal obstruction must not be overlooked and hygienic living in its broadest sense was of importance. Finally, we must avoid forming an exaggerated estimate of the difficulties experienced by left-handed persons in the ordinary actions of life. Such individuals became ambidextrous which in many ways was an advantage. The condition of brain and cord would improve if all their motor and sensitive elements were fully exercised therefore parents and teachers should encourage and train the free use of the right hand without suppressing the innate dexterity of the left.

A Study of Breast Feeding Possibilities in a Small Industrial Community.—Drs. Thomas B. Cooley and Wyman C. Cole presented this paper, which embodied the results so far obtained in a trial made under the auspices of the Babies' Milk Fund of Detroit of systematic propaganda for breast feeding conducted along lines almost identical with those described last year by Dr. Sedgwick to whom they acknowledged their indebtedness. Their design in making this trial on a small scale had been to form some judgment as to how far and in what form it might be desirable to apply this particular method of infant welfare work to larger communities; and at the same time to develop their method and to have a training ground for nurses. The locality selected was a small suburb of Detroit, comparatively isolated and peopled mostly by the laboring class. The birth rate in 1920 was 37.1 and the infant death rate for the same year was 8. An analysis of the statistics presented permitted of the following conclusions: (1) It was possible by propaganda of this type considerably to increase the number of breast fed babies, even in a community where the tradition of nursing the baby was evidently as strong as in River Rouge where this experiment was carried out. (2) The more brilliant results were obtained with women nursing their first babies, and special attention to this class would probably best repay one's efforts. Mothers of more experience were, however, often susceptible to instruction which enabled them to succeed after previous failure. (3) The work had extended over too short a time to show any effect on infant mortality. They believed from their brief experience that this special propaganda was a valuable adjunct to more common types of infant welfare work. It would, however, be of little use without the service of the special nurse, really well trained in breast feeding methods, and especially in ways of stimulating breasts whose production was inadequate. The statistics showed a remarkably high percentage of successful breast feeding from 96 plus per cent. at the end of one month to 83 plus per cent. at the end of six months. Their efforts had enabled some mothers to successfully nurse their babies after previous failures.

Myocardial Degeneration in Congenital Syphilis.—Dr. Alfred Friedlander of Cincinnati read this paper. He said that myocardial degeneration in infancy and in early childhood in very many instances rested upon a basis of congenital lues. We were accustomed to attribute myocardial degeneration in early life to certain of the acute specific diseases notably diphtheria, typhoid, pneumonia, and influenza, but we had not paid sufficient attention to the rôle of congenital lues in the production of myocardial degeneration. There was no typical form of myocarditis that might be recognized as luetic. The signs and symptoms varied in intensity in individual cases and were the ordinary ones—enlargement of the heart, feebleness of the first sound, and at times a systolic murmur at the apex. Arrhythmia was common. Typical auricular fibrillation was almost never seen in childhood. The Wassermann test was not always positive evidence even in well marked cases. It was interesting to note the rapid improvement of the cardiac condition in these cases under simple intensive antiluetic treatment alone. In many cases syphilitic myocardial degeneration might be the only manifestation of congenital lues. Warthin considered syphilitic myocarditis an important cause of death in early life, occurring often in apparently healthy children in whom syphilis may never have been

suspected clinically. Antiluetic treatment was suggested in myocarditis in young children irrespective of a positive Wassermann test and regardless of the fact that other definite signs of congenital lues were lacking.

Dr. BORDEN S. VEEDER of St. Louis said he was interested in this paper because of his experience in seeing several hundred syphilitic children in a few years. In about 500 cases he had seen only one aneurysm and hence he felt very doubtful about the syphilitic heart. He had not confirmed the findings of Warthin; he found that simply finding of the spirochete in heart disease did not necessarily mean that the condition was due to syphilis.

Community Health Centers.—Dr. J. H. MASON KNOX, Jr., of Baltimore presented this contribution, in which he said that Americans were a life-wasting people. The unnecessary high death rate was not appreciated by the average citizen largely because he had not had the effect of living under good sanitary conditions concretely proved. This was the idea of the health center. It was the application of approved methods of public and personal hygiene to all the people of a given community. It was the establishment on a small scale of an ideal health department for the purpose of demonstrating results. Such a center secured community service in health. Few of the many health centers already established were complete. The immediate problems must vary in different places. Where there were no public health activities, these were started *de novo*. In older communities the health center sought to coordinate and strengthen existing organizations and clinics, public and private. It was believed that when the results in improved health and happiness in a given area had been actually demonstrated the cause of public health in America would be furthered as was possible in no other way.

The Clinical Value of Intraperitoneal Injections of Salt Solution.—Drs. J. CLAXTON GIDDINGS and JOHN D. DONNELLY of Philadelphia made this presentation, in which they stated that in the dehydration seen so frequently in children suffering from gastrointestinal disorders with diarrhea during the summer months the most efficacious method of introducing fluid was by the use of the nasal tube or by intraperitoneal injections. The other methods were either too painful or allowed the introduction of insufficient amounts of water. The intravenous route possessed certain dangers and might well be reserved for the introduction of solutions of glucose or glucose acacia. The nasal tube was preferable to the stomach tube as being less likely to cause vomiting. It needed only to be introduced well below the epiglottis, but not through the cardia. This also seemed to be less apt to cause regurgitation. From 150 to 250 c.c. of water could be introduced two or three times in twenty-four hours, from three to three and one-half hours after the last feeding. Intraperitoneal injections seemed to be safe provided the bladder was empty the abdomen was not distended, and the fluid was introduced slowly. The amounts to be used varied usually from 150 to 300 c.c., the optimum to be judged by the subjective and objective symptoms. Disturbance of respiration and pulse and increasing distension indicated withdrawal of the needle. One hundred and sixteen patients received 352 intraperitoneal injections of saline solution. The oldest patients and those having the highest weight on admission showed the greatest proportion of recoveries. The mortality increased *pari passu* with the number of injections, being the highest in those who received ten or more. Dehydration was determined by the degree of loss of resiliency in the skin and subcutaneous tissues when pinched into a fold. According to this criterion those with the least resiliency showed the highest mortality, and *vice versa*, although in some cases the dehydration was entirely relieved without preventing the fatal issue. Autopsy upon nine of the patients showed that no injury had been done to the peritoneum or any of the abdominal structures. The authors concluded that the forced ingestion of water by nasal tube deserved a more extensive trial, that 300 c.c. probably represented a maximum for intraperitoneal injection in any infant under one year of age and that smaller amounts administered more frequently were safer for infants weighing less than 4000 grams.

Modes of Infection in Pyelitis.—Dr. HENRY F. HELMHOLZ of Rochester, Minn., called attention to the fact that as yet a correlation of the clinical, pathological, and bacteriological findings in pyelitis had not been established. It must be granted that examination of the urine in most instances would indicate a pathological process somewhere in the urinary tract, but that was all; it could not localize the lesion. It was impossible to differentiate the different forms involving the kidney cortex, pelvis, ureter, and bladder, singly or together. The pathological anatomy of these various forms of pyelitis was not well established and did not at the present time allow us to determine the mode of infection, except in those cases marked by cortical abscesses of the kidney. In a former series of experiments by Dr. Beeler and the writer the urine was found to be sterile in about 50 per cent. of normal patients and in 30 per cent. of patients with parenteral infection. In the study herein reported in which liquid media were used, cultures were sterile in 59 of 108 instances, and in solid media in 75 of 108 instances. To demonstrate the importance of bacteriological studies, Dr. Helmholz cited some of the pathological studies of kidneys that were sent by members of this society. These tissues were used to make serial sections of the pelvis of the kidney. No cultures of the different portions of the urinary tract were taken at necropsy, a matter which was of much importance. Clinically, the cases were definite examples of pyelitis; grossly and histologically they showed in serial sections an entirely normal pelvis. The pathological report in so many cases of pyelitis was negative that it seemed essential that bacteriological studies of the renal pelvis and bladder should be made in all cases of pyelitis that came to autopsy. In all of the writer's experiments in which he found peripelvic inflammation there was also found an infection of the urinary tract as evidenced by the presence of bacteria and pus within the lumen of the pelvis. The fact that in two-thirds of the infections of the pelvis, after intracystic injections, no periureteral infiltration was found, but only peripelvic inflammation and pus in the pelvis, showed that here, too, was a histological differentiation of the mode by which infection might travel from the bladder to the kidney. In the experimental production of pyelitism there was good evidence for the production of inflammatory conditions of the pelvis of the kidney, both of the hematogenous and ascending routes. The hematogenous method was very frequently associated with abscesses in the cortex of the kidney, but also in numerous instances by a simple inflammatory condition of the pelvis. There could be no question that cortical lesions of the kidney and pyelitis could be produced in the animal by the hematogenous route, by organisms of the coccus as well as of the colon group. The demonstration of the possibility of the hematogenous route of infection did not exclude any other route of infection. With regard to the direct passage of organisms from the intestinal canal to the kidney by way of the lymphatics it did not appear that sufficient evidence had been brought forward to warrant a discussion at this time. In view of the way in which the lymphatic system developed there was a possibility of a direct connection persisting in some cases.

Calcification of the Skin in a Child.—Dr. JOHN LOVETT MORSE of Boston reported this case, which occurred in a female child, born of poor and ignorant parents, who was normal at birth, and who walked at the age of 13 months. At 22 months she was sick for a week with what was called influenza. A month later she fell from a chair and soon ceased to walk. When a little more than two years old she was admitted to the Children's Hospital. At this time she was slightly rachitic; her nutrition was fair; she had eczema in both axillæ and behind the ears, and her tonsils were enlarged. Her hemoglobin was 59 per cent., white count 8400, and tuberculin test negative. She was treated for several months for lesions diagnosed as absorbing cutaneous abscesses. The Wassermann test was negative. The child was then lost sight of for a year. When 3½ years of age she was readmitted to the Children's Hospital, having been sick with a respiratory condition for about a week. She had a dermatitis of the scalp, the teeth were bad, the tonsillar fossæ showed necrotic tissue left from the tonsillectomy, and

there was a rachitic rosary. There were areas of induration at the borders of both axillæ, at the left elbow, in the upper thigh, buttocks, and in smaller areas in the popliteal spaces and on the calves of the legs. In some places there were numerous hard nodules scattered through the indurated areas. X-ray pictures of these areas looked as though they were filled with fine shot. Tissue from these areas was examined microscopically. The process was interpreted as primary degeneration of fat followed by calcification and repair by nonvascular organization without giant cell formation. An unusual feature was the absence of evidence of the formation of fatty acid crystals usually to be seen in fat necrosis. The product of the degenerated fat seemed to be a homogeneous hyaline material in which the lime deposited. The diagnosis was necrosis of subcutaneous fat with a typical sequence and calcification. The etiology was unknown. The microscopical appearances resembled the fat necrosis found in the abdominal cavity in acute pancreatitis, there the lesion of course being due to lipolytic ferment. In spite of the difficulty in accounting for the presence of such a ferment in the subcutaneous tissue, such a possibility must be considered in this instance.

Anomaly of the Kidney in a Child, with Sudden Uremia and Death.—Dr. HERBERT B. WILCOX of New York reported this case and presented the specimen. The child was a male infant of ten months, weighing 20 pounds, who had been well up to the onset of his present illness. He was admitted to the hospital suffering from an acute infection of the pharynx with cervical adenitis, otitis, and a temperature of 105° F.; the white blood count was 20,000. During his sixteen days in the ward he ran the usual course of such conditions and seemed to be slowly improving. He then developed sudden abdominal distention. An indefinite mass, hitherto unnoticed, was palpated in the lower right quadrant of the abdomen. Edema of the lower extremities developed, with vomiting and a rise in blood pressure, and death occurred twenty-four hours later. Autopsy demonstrated moderate edema of the feet and ankles, a distended abdomen containing 500 c.c. of clear straw-colored fluid. The findings were otherwise negative except for the kidneys, which were represented by an irregular nodular mass located in the midline at the level of the brim of the pelvis. This mass consisted of three kidney elements fused together, each with a clear line of demarkation between. There were numerous cysts throughout the kidney substance and sacculations of the pelves. The cortex, ½ inch in diameter, and the medulla, deeply congested were fairly well differentiated. The capsule stripped easily. A separate pelvis was found in each kidney element, these fusing into one dilated common pelvis, from which ran one large dilated ureter entering the bladder at the site normal to the right ureter. The left ureter was patent, and dilated for about one-third of the distance from the kidney to the bladder, and from this point extended to the bladder as a fibrous cord. The presence of three kidneys was a rare anomaly, but when occurring represented about 4 per cent. of the anomalies in these organs. There were a few recorded cases of supernumerary kidneys. The third kidney then usually was fused with the left and occupied the position normal to the left kidney. Fusion of the kidneys of all types occurred in about one in 10,000 autopsies. Nowhere in the literature since 1900 was any report found on the occurrence of the fusion of three kidneys. A kidney anomaly reported by Monquiot as lying transversely across the vertebra, having four ureters and four sets of vessels, was considered as possibly an instance of the fusion of four kidneys. Abnormalities of renal arteries were met with in about 25 per cent. of autopsies, and were frequently associated with developmental defects of the kidneys and ureters. Such abnormalities as these were thought to represent a throwback or reversion to the earlier types of kidney.

A Case of Dwarfism Associated with Congenital Heart Disease.—Dr. CHARLES HERRMAN of New York reported this case. He stated that cases of congenital heart disease associated with marked dwarfism were comparatively rare. In a series of 62 cases of congenital heart disease reported by Weber, only one was associated with marked dwarfism. The patient, 13 years of age, was the youngest of seven children, all but one of whom were healthy and of normal physical and mental development. The one child was not as strong as she should have been. The family history was negative. The patient was born at full term; the delivery was noninstrumental. The patient was small but not cyanotic. She was breast fed for eight months and began to walk at two years of age. She had always been small for her age, and not quite as strong as the other children. At five years of age she was taken to a physician on account of a cough, and the congenital heart lesion was recognized at that time. The child's mental development was normal. She had had none of the infectious diseases of childhood save an occasional cold. She was able to walk long distances without tiring, and to go upstairs slowly without becoming short of breath or cyanotic. Her appetite was fair, bowels regular. She had not begun to menstruate. The patient was markedly under size. Her weight was 49.5 pounds, corresponding to that of a child of seven years, the normal for her age being 91 pounds. Her height was 48.5 inches, corresponding to that of a child of eight years. The patient was not cyanotic, the fingers were not clubbed, but the hands were somewhat cool. The lungs were normal. The apex beat was felt in the fifth intercostal space, just outside of the nipple line. There was no thrill. The heart was enlarged to the right and there was an increased area of dullness in the second intercostal space to the left of the sternum. A loud systolic murmur was heard over the entire cardiac area, loudest at the third intercostal space to the left of the sternum; it was very well transmitted to the vessels of the neck on the left side, but poorly transmitted to the side. The roentgenographic examination showed enlargement of the heart, especially to the right. The ossification centers were apparently normal. The examination of the blood showed 90 per cent. hemoglobin and 5 136,000 red blood cells. The diagnosis of the exact nature of the lesions present in the congenital heart was extremely difficult. Defect in the ventricular septum with an open ductus arteriosus was the probable diagnosis. Almost all cases of congenital heart disease showed some retardation in growth, but usually it was not marked. The weight averaged from 10 to 15 per cent. below the normal for the age. A reduction of nearly 50 per cent., as in this case, was rare. As would be expected, the patients with marked cyanosis usually showed more retardation. It was therefore all the more surprising that the dwarfism should be so pronounced in this child, notwithstanding there was so little disturbance in the circulation. Although the physical examination showed no lesions in other organs, it was not unlikely that some other factor, possibly some other congenital anomaly, was responsible for the marked retardation in growth.

A Case of Meningitis Due to the Streptococcus Hemolyticus.—Dr. GEORGE N. ACKER of Washington reported this case, which occurred in a white boy, 12 years of age. He was sick for ten months on account of lack of breast milk and the fact that different foods given did not agree with him. During the second winter he had an attack of bronchopneumonia, after which he was nervous and in a state of malnutrition, but was somewhat improved after the removal of the tonsils and adenoids. During the third year he had severe inflammation of the bowels. Between the fourth and fifth years he had measles and chickenpox; at seven years a double mastoiditis, and three winters ago a slight attack of influenza. Two winters ago he had a more severe attack with earache and temperature for three weeks. His present illness began January 14, 1921, with pains in the right ear. For four days he had a remittent temperature and several hemorrhages from the ear. On January 22, in the evening, he had severe headache, vomiting, and pains at the end of the spine. His temperature went to 104° F.; in the morning of January 23 the temperature was 101° F., going to 105° in the evening. Hyperesthesia, photophobia, retracted head, and Kernig sign were present. On January 29, lumbar puncture. The fluid flowed by drops, but rapidly, 30 c.c. being removed. It was distinctly turbid on macroscopic examination. Microscopically it was found to contain an abundance of pus cells and fibrin, and a streptococcus. Culture showed a pure culture of *Streptococcus hemolyticus*. The lumbar puncture appeared to relieve the patient and was repeated several times. Until February 8 the

temperature continued to be high at night and lower in the morning; it was difficult to take the pulse, temperature, and respiration on account of the movement of the body, and the fact that the patient resisted any restraint. He was delirious at times and drowsy all the time. The head had been retracted, and pains in the head, back and legs were marked. There had been bleeding from the nose. He had taken large amounts of water and passed from five to six pints of urine daily. For several days he had nausea vomiting, and loss of appetite. Aspirin had had a good effect on the pains and bromide had been given several times daily for the nervousness. The pains gradually became less and disappeared. The boy grew stronger and at the present time was in good condition. Dr. Acker said that when he first saw the case he thought that the meningitis was secondary to the ear disease, but from the germ found he regarded it as a result of the influenza, as there were many cases of the disease at that time in the city.

Streptococcus Meningitis Treated by Repeated Lumbar Punctures, with Recovery.—Dr. HENRY L. K. SHAW of Albany reported this case, a virulent meningitis due to the *Streptococcus hemolyticus* Lumbar puncture was performed under anesthetic as often as was necessary. This was the only therapeutic agent employed. A complete recovery took place in eight weeks.

A Milking Machine.—Dr. ISAAC A. ABT of Chicago presented this apparatus, which had been constructed to secure an action which resembled the sucking action of the baby as nearly as possible. The machine was designed in such a way as to permit a variation in the intensity of the sucks and a variation in the number of sucks per minute. The machine consisted of a pump driven by an electric motor, with a coupling which could be adjusted so as to vary the number of pump strokes between 30 and 80. From the pump the suction was transmitted to a small milk-receiving chamber, which had a valve at the bottom. On the suction stroke of the pump the valve was closed and the milk drawn from the breast into the chamber. On the compression stroke of the pump the valve was opened and the milk discharged into any desired receptacle. The intensity of the suction was adjusted by a valve located at the pump and the amount of suction exerted on each stroke could be read from the vacuum gauge which was connected with the pump.

A Case of Encephalitis in the Newborn.—Dr. B. RAYMOND HOOBLER of Detroit reported this case, a baby first coming under his observation when three weeks old, with the history that though apparently normal it slept for periods of twenty-four to thirty-six hours, and could hardly be aroused for its food. The baby did not cry like other babies, and the mother's keen eye noted that there was an exceedingly placid expression about the baby's face. Ptosis of the left eyelid was noticed from the first day, but this was thought to be a family inheritance, as some relative had a fallen lid. Shortly afterward there was considerable difficulty in swallowing. At the end of the third week convulsions, general in character, started. These were at first very severe, ending with an agonizing cry. When first seen by the writer there was typical myoclonus. A tentative diagnosis of encephalitis was made having also in mind the possibility of a birth injury. Various laboratory observations were conducted: an *x*-ray of the skull, spinal puncture, blood and urine analyses, cultures from washings of the nasal cavities, all of which were negative. The spinal fluid was not under pressure. The Wassermann was negative. The eye grounds showed a slight haziness of outline, but no choked disc. The case had been under observation nine weeks. During this time the convulsions had become much less frequent and very mild in character. Nystagmus had been present for a few days in the seventh week. Strabismus, both convergent and divergent, was present during the first three weeks of the convulsive period. The ptosis which at first was marked was now slightly noticeable. There was no longer difficulty in swallowing. The extremities had at no time shown paralysis. The knee jerks were active. During the seventh week there developed fibrillary twitchings of the eyelids, cheek muscles and over the abdominal wall. The amount of lethargy present had varied greatly. In the ninth week of the disease the child had seemingly recovered from its lethargy and now awakened for its feedings, and often lay awake for periods as a normal infant should. All the functions had been normal and the child had gained steadily in weight and now had all the appearance of a healthy child. The mother related that during the time she was pregnant, at least during the latter half of pregnancy, she was at times so overcome with the desire to sleep that she would drop on a couch after her husband would leave in the morning and would sleep the greater part of the day. This was ascribed to biliousness, and nothing was thought of it. So far as he could ascertain, Dr. Hoobler said the mother showed none of the typical symptoms of lethargic encephalitis, and only when the baby developed the symptoms was anything thought of the drowsiness of the mother during pregnancy.

Lymphatic Leucemia in a Child.—Dr. L. E. LA FETRA of New York presented this report. He said that the report was presented because although enlargement of the lymph nodes and spleen were very common in childhood, involvement of other organs was, in his experience, very unusual. The laboratory findings corresponded to those found in lymphatic leucemia. The important findings were enlargement of the thymus, enormous spleen and involvement of the liver, kidneys, retroperitoneal glands, adrenals, and practically all the viscera. The organs showed an enormous general infiltration with lymphocytosis.

A Case of Rumination.—Dr. PERCIVAL C. EATON of Pittsburgh reported this case, which was admitted to St. Margaret's Memorial Hospital, May 4, 1921, at the age of six months. The child appeared perfectly normal at birth and weighed 8 pounds. It was then given a feeding of cow's milk and water, equal parts plus the breast. At two months of age the breast was discontinued. Then for a while cow's milk, water, and lime water, and then barley water and milk equal parts, the top of a quart of milk after standing being used. The baby then began spitting and regurgitating regularly and with increasing frequency. The child was then put on condensed milk, and two days before coming to the hospital, on Horlick's milk. There was constant sucking of the fingers and fists noticed on arrival at the hospital. For the first two days the child regurgitated all food. The bowels were constipated and the stools offensive. The child was cleaned out and put on a proper milk formula. It was found that if he lay on his side he lost all his food, but if kept on his back he did not lose nearly so much. To prevent him keeping his fingers and fists in his mouth all the time his arms were put up in splints. He still regurgitates, but not so much. Upon careful observation it was noticed that he would bring food up into his mouth, sometimes spitting out a little and sometimes retaining all of it in his mouth, chew it, and then swallow it. As an experiment his hands were allowed to go free and he seemed to use them to facilitate the bringing up of his food. Thereafter his hands were kept away from his mouth and he ruminated less and less, and at the time of leaving the hospital was losing little of his food. His color had improved and on May 30 he weighed 9 pounds 10 ounces. Dr. Eaton said he had never seen a case of this kind. In looking up the literature he found in the February number of the *American Journal of Diseases of Children* an article on "Rumination," by August Strauch, which was very complete, and in the May issue of the *Archives of Pediatrics* he had found the report of a similar report by Dr. Kerley.

Report of Female Infant with Double Inguinal Hernia.—Dr. H. M. McClanahan of Omaha reported this case. He said the mother first noticed a swelling in the right groin when the child was five weeks old. The following day a similar swelling was noted in the left groin. These swellings were diagnosed as double inguinal hernia. About four weeks later a small round mass appeared in the left groin that could not be reduced. At operation this sac was found to contain the fallopian tube and left ovary. The ovary was almost purple, but not strangulated. It was returned to the abdominal cavity. The hernial sac was removed and the canal closed in the usual manner. The infant rallied well after the operation and made a good recovery. The hernia on the right side was retained by means of a truss.

Miscellany.

Death of Zuckerkandl.—This distinguished Vienna urologist died on July 1 from the effects of an apoplectic stroke before the completion of his sixtieth year. Having graduated in medicine in 1884, his earliest professional years were devoted to surgery as assistant first to Albert and then to Dittel. It was not until 1902 when he became surgeon-in-chief to a newly erected Israelitish hospital that he changed from general surgery to surgical urology. Two years later he became ordinary professor of this branch in the University. His bent to urology was, however, doubtless the result of his early association with Dittel, whose perineal prostatectomy he adopted. The Dittel incision is said to have originated from the joint labors of the older and younger man. At this juncture Freyer began to publish his work on the suprapubic approach and Zuckerkandl, instead of adhering to his own operation, as usually happens in such cases, immediately set about to test the other. The result was that he became a convert to the suprapubic route. This sort of attitude toward a rival is as rare as it is praiseworthy. The deceased added several undescribed urological diseases to our nosology, as closed tuberculous pyonephrosis and fibrosclerotic paranephritis. With Frisch he published the large handbook of urology which marked an epoch in the evolution of our knowledge. During the great war he was in charge of a great military hospital in Galicia (Lemberg), but upon the suspension of hostilities he returned to his lifework of elevating urology to a full surgical specialty, and in 1919 was elected first president of the new Vienna Urological Society. He was equally at home in the major surgical interventions and the most subtle endovesical work, and leaves many former pupils who are now eminent urologists throughout the world.—*Wiener klinische Wochenschrift.*

Female Circumcision Among the Nubians.—Frohlich contributes an article on this subject in the *Schweizerische medizinische Wochenschrift* for August 25, 1921, li, 34. He begins with a résumé of the writings of others and passes to the results of his own nine years' observations as a medical missionary in Upper Egypt and Nubia. He believes that he has acquired a much more intimate knowledge of the Nubian than has any European predecessor. Naturally it is not enough to observe from the outside, for one must have gained the full confidence of the natives. He writes principally of the operation of circumcision and infibulation in females, basing his account on the results of examining many girls and women. He states that as a religious rite of the Mohammedan religion practically every female child is subjected at the age of 4 or 5 to complete circumcision—total ablation of the external genitals. The child is held tightly by several women during this ordeal, as she lies crosswise on the bed with lower limbs abducted. The village barber or midwife officiates, and with two powerful sweeps of the razor the majora, minora, clitoris, and at times the tip of the urethra are slashed off, leaving a wedge-shaped loss of substance. Hemorrhage is severe and at times fatal. Ashes are applied to the defect, or of late years iodoform. A goosequill or wooden tube is then inserted in the lower angle of the wound and the latter is closed with an ordinary sewing needle of large size and thread, while the lower extremities are bound together. Forty days are allowed for healing, the urine finding its way into the drain. The bandages are then removed and the child resumes active life. At the end of 10 or 12 days she is allowed to get about as well as she can with bandaged limbs.

After this operation the vulva is seen to be occupied by an ugly scar with an orifice large enough to admit the little finger. This is the introitus vulvæ. Of the meatus urethræ nothing may be visible. A photograph is given of a 12-year-old girl but it is on too small a scale to be illustrative. This patient had bilharziasis of the rectum, which enabled the author to study the vulva. The girls are usually married off at the age period 12-14. The defloration following marriage is one of the most cruel tortures devised by man. Six powerful women hold the bride if she is strong, three or four may suffice if weak. The husband, coached by the midwife, begins by introducing the index finger anointed with beef tallow. Gradually the other index is inserted alongside of the first. The groom perspires from his exertions as the bride bleeds, sometimes to death. Rupture of the perineum in the second or third degree is common. The bride screams in agony and may be in collapse from pain, with the bed soaked in blood. The women who officiate give a sort of dance of jubilation after the success of the operation. Coitus is not attempted until after 4 to 7 days. There is no privacy even here. Women crowd into the bridal chamber and perch on top of the walls. Those not officially present are chased away, and the groom shies brickbats at the peeping heads. The women, despite the mutilation, show the same sexual craving and pleasure as the intact black female.

The rationale of total circumcision goes back to antiquity, and no one can fully explain it. In all probability it is the same as for circumcising boys —to preserve against the consequences of irritation and inflammation which in turn are the natural consequences of habitual uncleanliness. Women who escape this ordeal are unmercifully mocked and scoffed at. If the child die of the operation it means some special privileges in the Mohammedan heaven.

In Honor of General Gorgas.—In the Cuban official sanitary periodical *Sanidad y Beneficencia* for April-June, 1921, xxv, 4-6, is an account by Dr. Lopez del Valle of the honors paid by Cuba to the late General Gorgas. This homage took the form of changing the name of Virtudes Street in Havana, one of the principal and most popular thoroughfares of the Cuban metropolis, to Gorgas Street—*Calle General Gorgas.* The formal ceremony took place last March and consisted of publicly replacing the former street signs with new plates which announced the change of name. The substitution was really made in advance in private and then veiled so that the public ceremony consisted in unveiling the new name plates. This was done on a Sunday morning in the presence of the local authorities and diplomatic corps. An oration was then delivered by Dr. Lopez del Valle, the executive health officer of the city and an old personal friend of Gorgas, whose successor he became.

SHOCK AND FATIGUE WITH ACUTE AND CHRONIC (CYTOST-ANTICYTOST) REACTION.*

BY FENTON B. TURCK, M.D.,

NEW YORK.

THE topic with which we are dealing in this paper is largely of a biological character. Although the deduction derived from experimental work and certain hypotheses is applied to theoretical and practical medicine it is easily understood that any fundamental changes in the theory and practice of medicine require work which refers back to action and reaction on single cell bodies (protozoa), because the higher animal life is in many regards only a multiplication of phenomena exhibited in the monad organisms. Practically all the changes produced by the substances to be described later are of a physicochemical character. Like most biological products the exact chemical nature of the causative agent is unknown, but this does not curtail the very plain biological effects which one can determine even quantitatively in a manner so ofter used in toxin and antitoxin work.

The work on shock and fatigue phenomena, and on acute and chronic conditions caused by certain biological products originating from tissue breakdown and autolysis, dates back twenty-five years (1896), and certain fundamental experiments leading to the hypotheses mentioned later on were made a few years prior to this date. Although a large number of publications on various clinical and experimental items referring to various branches of medicine were published in the course of years, it is, nevertheless, plain that the entire series of observations show a logical course and a continuous upbuilding on a basis which underlies most phenomena of acute and chronic injury to the animal body. British and French writers have taken exception to the theories explaining shock or fatigue as exhaustion symptoms of the central nervous system, but no clear-cut experimental and clinical evidence has been produced to show that these pathological changes are solely due to toxic effects caused by cell destruction and the liberation of a toxin. Besides, only reactions of an acute type were studied, while our work deals also with the chronic effects of cell destruction and with the stimulant character of the substance created by tissue breakdown through mechanical and chemical injuries and also through cell autolysis. As is to be expected most theories dealing with toxic action and reaction are principally based on protein action. We shall show however that this is a misunderstanding regarding the nature of the causative agents since we produced the entire variety of phenomena, excluding the proteins by incineration of the products derived from the injury. The dissolved water-soluble remnants show plainly that reaction can be measured not only by physical means, but seem to be of a physico-electrical nature. The toxic products require a specific but always uniform mode of preparation, their application, however, varies with the effect to be produced.

If the toxin is applied to the animal (or protozoal body) in very small doses and at long intervals of time it will produce stimulant effects which will be explained later in this paper, while large doses, introduced into the animal body once or several times at short intervals, would produce acute shock or death. The products derived from the broken-down cell body in cases of mechanical or chemical shock we denominated "shock toxin" or with reference to the symptoms produced "fatigue toxin" (in 1897). Various names have been applied to this substance (metabolites and others). Since the product is exclusively derived from the cells *i.e.* from protoplasm as well as from the nucleus, I have named it "cytost" and the antagonistic agent produced by immunization with cytost I called "anticytost" (*cytos*, cell). It is not feasible to include all references and the various studies on this subject at every part of the following discussion on the matter so we have to refer to the literature which is added to this article.

Goltz in 1857 advanced the theory that changes of a central nervous system caused the symptoms of shock, which on the other hand was accompanied by splanchic stasis and death. He referred largely to mechanical injuries producing shock, while later on, Crile in America vigorously championed this theory since his Cartwright Lectures in 1898 up to the present time. All experimental work and the tragic clinical lesson of the war had proven that the theories of "nerve cell exhaustion" as the origin of shock are absolutely untenable. We must conclude with Kocher's (1916) statement that "the Crile theory of shock is an assumption based on insufficiently controlled experiments." (R. C. Kocher, "The effect of activity on the histological structure of Nerve Cells," *Jour. Compar. Neurology*, xxvi, 3, 1916.)

Our early research work on shock extending from 1893 to 1918 proved that no shock was produced except by the passage of the tissue toxin, or, as I called it in 1897, "shock toxin," to the splanchic zone which causes stasis in this area and death. The fundamental experiment which I have since

*Read before the Canadian Medical Association (Pathological Exhibit), Halifax, N. S., July, 1921.

repeated many times demonstrates this fact in a very simple way. If we make a flesh wound and extract the injured tissue product (cytost) by water or the above-mentioned incineration method and injected into a vessel of an animal of the same species, the animal dies within three seconds. Sections taken from the splanchic area of this animal show blood stasis in the splanchic zone with effusion into the surrounding tissue. The same effect with the production of the shock syndrome, as well as the pathological changes, we have found in animals which were injected with liberated tissue fluid caused by the injection of ether, chloroform, and alcohol. If, therefore, we injected animals intramuscularly with the afore-mentioned chemicals, the tissue extract from these muscles injected into animals of the same type produced typical shock symptoms. Alcohol seems to differ from ether and chloroform so far as the duration of action is concerned, since the removal of the latter two chemicals stopped the shock effect, while in the case of alcohol, the effect kept on for some time later. French and English writers have alluded to our work in various treatises on shock and toxemia, and I wish to mention only a few of their statements. G. Jeanneny of the University of Bordeaux who has particularly devoted himself to the subjects of the toxic products of cell necrosis has summarized his work as follows: "The Americans seemed to have surpassed us in this field. F. B. Turck of New York, who, since 1896, has devoted himself to the subject of the toxic products of cell necrosis (autolysis) and practices a prophylactic treatment of shock and even of numerous infections of a similar nature":—(Acad. de Méd., May 20, 1919).

The serum of horses immunized against the "autolysat" is antitoxic in shock as is proven by experimental and clinical facts. (Proc. Soc. d' Anatomie Clinique de Bordeaux, Feb. 9, 1920, also Mar. 8, 1920; *Gaz. Hebdomad. des Sciences, Méd. de Bordeaux,* 1920). We must conclude with Halliburton to quote direct (Halliburton, 1921, *Lancet* Mar. 26, 1921, "The Importance of the Infinitely Little") that it is inevitable to accept the view that shock is a condition of toxemia. The poison is produced by tissue breakdown. The blood becomes stagnant and is sidetracked in the capillaries." This is the conclusion of Prof. J. J. R. MacLeod of Toronto (MacLeod, Physiol. & Biochemistry in Modern Med. 3d edition, Page 310, 1920). After a review of all literature with clinical and experimental facts he states that "surgical shock is essentially due to intoxication by materials derived from damaged tissue. All clinical facts conform admirably with the experimental findings. The above conclusions are more or less confirmatory of those drawn several years ago by Turck (1897-1902) to whom credit is due for being the first to suggest the toxic element as the causative factor in shock."

Quenu wrote as follows: "Opinion is growing that shock is due to poison resulting from wounds rather than from nervous affection. As Turck has shown in a medical review on "The Primary Cause of Shock," the toxic albumins are formed very rapidly by auto digestion of traumatic tissue. This opinion of Turck coincides with our own opinion."

During the Napoleonic war Larry, a French surgeon, was the first one to recognize the importance of débridement as a means of reducing wound shock and this measure has greatly improved mortality statistics, but it was not until the recent world war that this procedure has found general recognition among the surgeons of the allied armies. Thanks to the wide use of débridement the mortality from shock dropped from 75 per cent. to 9 per cent. Although the extensive literature which I published on this subject since 1896 appeared in English, German, and French medical journals the toxic origin of shock was rediscovered by a number of authors. Cannon (*Jour. A. M. A.,* Mar. 2, 1918) stated "Primary wound shock, dusky pallor, rapid thready pulse, sweating, thirst and restlessness, may come on so soon after injury as to be accounted for only as the result of nervous action." The organization of the individual for example he states (a highstrung temperament) fear, and fatigue probably provide favorable conditions for the nervous response." Cannon later modified this idea and admitted that apparently victims of shock are poisoned which may, he added, "cause death by rapid action on the nervous system or other organs" (Soc. Biol, Paris, *J. A.M.A.,* Dec. 28, 1918, p. 2166).

The work of the writers on shock, however, must remain unsatisfactory so long as the actual toxin is not produced and no proof is given for these substances causing the typical symptoms. Our experiments which have been made repeatedly on numerous types of animals, prove conclusively that the product of the devitalized tissue (cytost) is toxic to animals of the same species. If the amount of cytost liberated through the injury is not sufficient to cause acute symptoms, a chronic type of shock or extreme fatigue and debility may follow. If we immunize animals with a certain amount of cytost (ash remnants of autolyzed or devitalized tissue) we are able to produce a serum which will counteract the effect of cytost. This substance we call anticytost. We titrate the anticytost by its capacity to balance the action of cytost. The strength of the latter is measured by its electrical conductivity. To express these terms in words generally used in biological pathology, it is an antigen-antibody reaction. The antigen is the cytost delivered by broken-down cells in which it was held in balance by anticytost and liberated through any sort of trauma (mechanical, chemical, or by ferments). The antibody is anticytost which cannot be liberated by the cell unless we stimulate it by the antigen. An excess of cytost in the animal body causes acute or chronic diseases according to the amount liberated and the disposition of the animal body. In certain cases, the slower action of cytost will produce senescence, and a summary of experiments on protozoa (*Paramecium*) might give an illustration of the action of cytost on these single cell organisms which was, in other experiments proved on multicelled animals (metazoa).

When cultures of protozoa, as *Paramecium,* grow luxuriantly and multiply too rapidly in a single colony, they begin to agglutinate into a compact body and finally die. The cause for this agglutination and death seemed to be due to the degradation products of the overcrowded cultures. This was proved by preparing the extract of dried paramecium (cytost) and adding this concentrated ex-

tract of paramecium cytost to the ordinary culture. All the paramecium cells died in a few hours. The control, by adding extract from other animal cells, was negative. Low concentrations of paramecium cytost added to cultures, stimulated activity and growth, but excessive accumulation of homologous cytost caused death of the colonies. On the addition of paramecium extract (cytost) in excess, to the fresh cultures of paramecium the protozoa, instead of darting from one end of the field to the other, begin to move in a circle more and more confined, and finally rotate on their own axis. They become more spherical in form, come to a standstill, and the whole colony dies. The addition of food does not prevent the order of events. Therefore this is not a starvation phenomenon nor do the protozoa die from diet deficiency or want of oxygen. This phenomenon was produced by the addition of cytost in excess and was made to occur early in the culture before it had assumed such prodigious growth to form a large colony. The same result was accomplished by adding physiological concentrations of cytost but at more frequent periods. This resulted in the agglutination, "spinning" of each individual protozoan, and finally spheroidicity, encystment, and death. This was not influenced by bacteria for protozoa depend on bacteria for digestion of food. What occurs in colonies of the protozoa takes place in tissue cultures of metazoa—chick or human culture. The condition which is produced in paramecium cultures which could properly be termed senescence is a symptom of "old age" and can be similarly demonstrated in metazoa. I shall give in the following lines certain examples taken out of the protocols comprising numerous experiments. They show stimulant effects on small doses of cytost given in long intervals, senescence and death upon rapid injections with large doses.

Three young normal kittens of the same litter were selected. Cat "A" was injected with physiological concentrations of cat cytost—once a week or one in ten days—the biological interval. It grew rapidly in size and weight and increased in metabolic activity over the control.

Cat "B" was injected with the same physiological concentration of cat cytost, but with this difference, the injections were repeated every other day or every day instead of once a week or ten days. Results: Progressive decline in weight and general metabolism, finally rapid senile changes and the young kitten became as an old decrepit animal and died of "old age" with arterial sclerosis, fibrosis of the kidney, liver, and lungs. There was also general atrophy, arthritis, and neuritis, although the animal was only seven months old. From this experiment, as well as from similar ones, the deduction is at hand that senescence is not a normal status, but depends on the accumulation of cytost. We have also shown that by experimental injection of anticytost the senescent effects might be prevented or delayed.

In making a brief survey of the condition caused by excess of cytost in the animal body, we find that they are grouped as follows: (1) Shock (mechanical, chemical); (2) Chronic disease (paralysis, neurotic and toxemic conditions, pneumonia, and arthritis); (3) Prenatal condition (hereditary debility, caused by toxic condition of the mother). Stimulating action by overproduction of anti-cytost, increased vitality, overgrowth in general.

As was explained before, anticytost in excess of the cytost present in the cells of the body can be created by cautious immunization with homologous cytost (cytost specific to species). The injurious action of cytost shows three degrees according to the quantity used, and the latter is determined by electrical measurements. In order to abbreviate expressions of quantity we proposed the following letters substituting amounts of toxin: L. C., Low concentration; M. C., Medium concentration; H. C., High concentration.

The anatomical findings in autopsy cases of acute or chronic conditions caused by excess of cytost show a rather uniform picture. The most significant changes are the dilatation of the blood vessels in the splanchic area with subsequent stasis, effusion into the adjoining tissue, extensive mitotic changes in these areas, and conglutination of the blood.

The application of cytost to the animal body (metazoa) can be made hypodermically, intravenously, or by insufflation into the respiratory tract. In the latter case cytost should be directly applied to the mucous membrance without injury of the mucosa in order to exclude any objections to this method which in case of an application to the submucous tissue would not deserve the name applied to this method.

According to the situation of cytost we distinguish: (1) Endogenous cytost. (2) Exogenous cytost.

Endogenous cytost is present within the cell body, exogenous cytost is extracellular, produced either by an irritant or by direct application to the animal body which liberates cytost.

The presence of an excess of endogenous cystost manifests itself in: Adolescence in the male: climacterium in the female; menstruation in the female.

Excess of endogenous cytost is also exhibited in toxemia of pregnancy which effects mother and fetus causing: (1) Prenatal death; (2) Death of the newborn; (3) Congenital diseases.

These afflictions are all due to a lowered resistance caused by a deficiency of anticytost.

General activity of endogenous cytost:

Over-activity—"Fatigue toxin," Under-activity—Production of metabolites, "waste products."

Local activity which also produces changes due to over-activity and under-activity.

Exogenous cytost can effect the animal body by direct contact with other individuals since epithelial "dust" as well as all excreta and secreta contain liberated cytost.

The hands, clothes, and utensils which come in contact with human bodies may contain free cytost, also vitiated air produced by expiration which is particularly noticeable in cage experiments made in animals. The same source of liberated cytost is noticeable in cantonments, barracks, and other closed localities.

Contact with human cytost is also responsible for the spreading of the influenza and of pneumonia.

Shock is produced together with the liberation of cytost in: Physical trauma; high air pressure mechanical trauma.

It is assumed that caisson disease and pneumonia are due to rapid production of cytost.

Liberation of cytost by perturbed alimentation: Total starvation—toxemia with cell autolysis;

Partial starvation—deficiencies of the diet, particularly lack of vitamines, salts, and caloric values in general; Excess pabulum interrupts digestion, absorption, and assimilation which is potentially partial starvation. The waste products are not burned up by the anticytost in the body.

Conclusions.—Injuries to the animal cell body, in protozoa as well as in metasoa, liberate a substance which we call cytost. This substance is specific to the species and therefore shows its activity only in homologous cells or cell complexes.

This substance can be set free from the cells in which it is normally balanced by a counteracting substance named anticytost. The experimental production of cytost can be caused by mechanical or chemical means.

The phenomena created by cytost are of a physicochemical character. The quantity is determined by physical (electrical) means only. Protein activity is excluded because the cell product is incinerated in order to produce the dry substance containing cytost.

Cytost is a biological product, since immunization with this substance produces anti-cytost which is then present in the serum of the animal. It is therefore strictly an antigen-antibody reaction which produces symptoms of a definite nature.

The pathological changes caused by excess of cytost in the animal or protozoan body are of a toxic nature and the phenomena produced show no injury to the central nervous system which could be accused of being the origin of the pathological change.

The principles advanced in this article explain: (1) Acute pathological conditions—shock, eclampsia, gravidarium, toxemia of pregnancy; (2) Chronic diseases, as arthritis, neuritis, metabolic disease, chronic toxicity, ulcers of the stomach, hereditary afflictions caused by toxic conditions of the mother; (3) "Infectious diseases," pneumonia, influenza; (4) Symptoms of total or partial starvation through over- or under-activity of cytost, constitutional diseases, rickets, and general debility.

Summary.—1. The typical experiments here described are a part of the experimental and clinical research work of the last twenty-five years which are embodied in the system of biological pathology. The appended literature contains the matter indicated by titles on the various topics.

2. The principles of this work have been generally adopted by other writers. Although not always accompanied by the experimental evidence.

3. Cytost is the final court of appeals for the determination of cell division and metabolism of time and order, of growth and decay, of rejuvenescence and senescence, and correlations of widely separated phenomena in the change of the biological system. This is the basis on which rests Dynamical Biology. The experimental data on cytost-anticytost reactions with résumé of previous experiments, may be more completely followed by reference to the writer's recent article in the MEDICAL RECORD, July 2, 1921.

Bismuth as an Antisyphilitic.—Sazerac and Levaditi made use of the tartro-bismuthate of sodium and potassium in very recent syphilis and saw the treponemas disappear in a few days with recession of adenopathy. The Wassermann became negative and remained so. Bismuth, like mercury, can cause stomatitis.—*La Presse Médicale.*

OBSERVATIONS REGARDING THE SURGICAL TREATMENT OF SELECTED CASES OF PURULENT MENINGITIS.

By WILLIAM SHARPE.
NEW YORK.

THE field of neurologic surgery is constantly being enlarged as a result of the earlier and more accurate diagnosis of intracranial conditions, thus permitting a more favorable prognosis than is possible when the operation is postponed and then finally advised as a "last resort"—"the patient is going to die without an operation and possibly an operation will give him a chance." It has been this delay of weeks and even months in conditions of brain tumor, and of hours and even days in conditions of intracranial infections, such as brain abscess and purulent meningitis secondary to a cranial infection, that has permitted these patients to become not only permanently impaired mentally and physically in the event of recovery of life, but to reach a moribund condition where it is most unusual for a recovery of life to be obtained—whatever the treatment; to advise a cranial operation at this late stage merely tends to discredit neurologic surgery, on account not only of the resulting high mortality, but of the slight improvement possible in intracranial conditions which have been permitted to continue to a degree that the patients have in reality become derelicts. These latter conditions are chiefly those of brain tumor with its frequently associated blindness, and of brain injuries, particularly intracranial hemorrhage of the new-born in whom the resulting increase of the intracranial pressure, if not relieved, prevents a normal mental and physical development, even to a degree that a large percentage of these children become imbeciles. It is, however, in the acute conditions of purulent meningitis and especially those secondary to a cranial infection, such as mastoid and sinus disease and infected fracture of the vault and of the base of the skull, that it is obligatory for the appropriate treatment to be instituted at the earliest possible moment. This paper will be limited to the surgical treatment of selected cases of purulent meningitis secondary to a cranial source of infection, and is the result of observations in a series of 31 patients.

Let it be definitely stated for fear of any misunderstanding, that patients who have developed a diffuse and general purulent meningitis from a cranial focus of infection are, in my opinion, beyond the surgical relief of drainage and it is only in the rarest of cases that a recovery of life is possible, operation or no operation. To advise a cranial operation to remove the primary infective focus in the mastoid, accessory sinus, et cetera, or to drain the purulent cerebrospinal fluid in the hope that the patient may then "take care of" the infective process at this late date and after the condition has become one of diffuse meningitis and involving both the brain but also the spinal cord, not only gives the patient no real chance to recover, but even lessens his resistance to the infection and thus hastens the exitus. No doubt, case-histories have been reported in which the exceptional patient has recovered with life even after the development of a diffuse purulent meningitis, with and without operation, but they are most rare and particularly when it is remembered that the differential diagnosis of a profuse purulent meningitis has been accurately determined only within the past few years; that is, conditions of meningeal irritation, meningismus, and localized meningitis have frequently been confused with the true condition of diffuse purulent meningitis merely because the cerebrospinal fluid at lumbar puncture was turbid and cloudy from an increased number of cells, together with the clinical signs of stiffness of the neck and a positive Kernig test. Unless the pathogenic bacteria of the cranial infection are found in the cerebrospinal fluid at lumbar puncture, then the diagnosis of a diffuse purulent meningitis cannot be made—no matter how turbid with cells the cerebrospinal fluid may be, nor how rigid the neck, nor how positive the Kernig test. These latter signs indicate a meningeal irritation of varying degree, but if no bacteria are present in the cerebrospinal fluid at lumbar puncture, then the infective process can still be considered as a localized one, and it is these patients who can be offered a definite chance of recovery by means of a nearly cranial decompression and drainage of the purulent exudate. To permit patients, however, to enter this critical condition of meningeal involvement without the most careful examinations, and particularly the use of repeated lumbar punctures, in order to ascertain as early as possible the actual intracranial condition—this attitude of apparent helplessness is most probably due to the current belief that if a purulent meningitis does develop, there is no means of preventing it from becoming a diffuse process and therefore a fatal one, and that the treatment is purely of an expectant palliative character. If the condition is one of diffuse purulent meningitis due to the extension of a cranial infection, then this attitude is only too true, but the patient should not be considered as being beyond help unless the cerebrospinal fluid at lumbar puncture discloses bacteria. It is this differentiation of patients that I wish to discuss in this paper.

In the civil industrial life of peace-times, the most frequent cranial focus of infection producing by its extension intracranially a diffuse purulent meningitis is, first, in the mastoid, and, secondly, in the accessory nasal sinnses; compound fractures of the vault and of the base of the skull occasionally permit the entrance subdurally of pothogenic bacteria with a resulting purulent meningitis, but these latter cases are rare compared with the great frequency of purulent meningitis following mastoid and sinus disease. In the operative treatment of the local condition, and in the absence of any intra cranial complication, it is naturally essential to remove the local infective process and to establish free drainage externally, and in the vast majority of these patients, this local treatment suffices to obtain an excellent recovery. It is only, however, when the patient "does not seem to be doing so well as he should," and especially in the presence of severe headache and a quickly rising temperature, that the most careful examinations should be made. If examinations of the local operative area are negative and there is no cellulitis of the adjacent tissues, the greatest care must be used to expose the underlying dura and thus eliminate the possibility of an

extradural abscess being present. If these local examinations are all negative and no other systemic conditions can be found to account for the rising temperature, headache, malaise, etc., then the probability that the infective process has extended intradurally must be considered. Now is the time, at this early date, that a lumbar puncture should be performed—not for the purpose of removing a large quantity of cerebrospinal fluid, but merely to obtain a small amount (not over 2 c.c.) so that the pressure may be noted and the cell count made, and thus disclosing the meningeal involvement, if present. To postpone the examination of the cerebrospinal fluid until the neck becomes rigid and a positive Kernig test is obtained, and the ophthalmoscope discloses an edematous blurring of the optic discs from a marginal edema to a measurable papilledema and even to a degree above 2 diopters ("choked disks"), and the temperature reaches a height of 104° plus—all the signs of a serious meningeal infection—cannot be condemned too strongly; to wait until the diagnosis of "meningitis" can be certified by the above clinical signs is permitting the patient to reach a most dangerous condition, from which only a small percentage recover, even with operation and only those in whom the cerebrospinal fluid at lumbar puncture is still free from bacteria.

Naturally, a negative report of a stained specimen of centrifugal cerebrospinal fluid is not so reliable and accurate as a negative culture, and yet if a delay of 24 to 48 hours is permitted for the report of the culture, it is frequently too late to advise an operative drainage, because the cerebrospinal fluid at lumbar puncture has become positive during this waiting period of hours. Once bacteria are found in the cerebrospinal fluid at lumbar puncture, then the treatment matters little, as these patients, with the rarest exceptions, all die. If bacteria should be found in the cerebrospinal fluid at lumbar puncture, then no operative drainage is indicated, and any operation, cranial or spinal, merely tends to discredit neurologic surgery.

The test of lumbar puncture, as now performed, no longer entails a greater risk than that necessary to obtain blood from the arm; naturally, absolute asepsis is obligatory and the quantity of cerebrospinal fluid to be removed should not exceed 2 c.c.—an amount sufficient for all of the tests, including that of the Wassermann reaction. In this manner, the danger of precipitating a medullary (bulbar) compression in patients having a high intracranial pressure or of facilitating the extension of the cranial meningeal infection into the spinal canal by the removal of a large quantity of the spinal cerebrospinal fluid, is thereby avoided. A lumbar puncture properly performed is not only without risk, but under local anesthesia, it is usually without severe pain, and therefore the former objections to its extensive use are no longer valid. In these most serious conditions of possible meningitis, with its high mortality, the slight risk and possible momentary pain and discomfort from the lumbar punctures cannot be offered as rational objections to the early use of this most important test. The importance of the early diagnostic use of lumbar punctures is true not only of meningeal infections but also of suspected intracranial hemorrhage in new-born babies following difficult labor and in those patients having severe cranial injuries with or without a fracture of the skull. If a lumbar puncture reveals bloody cerebrospinal fluid under only a moderately increased pressure—not over 16 mm. as measured by the spinal mercurial manometer, then the repeated lumbar punctures of spinal drainage will frequently be a sufficient aid to the natural means of absorption under the expectant palliative treatment to permit an excellent recovery, both of life and of future normality. No cranial operation of decompression and drainage will be necessary unless the pressure is above 20 mm., and the operative method is then always the safer procedure. In a series of over 1,000 patients, the expectant palliative treatment was thus indicated and eminently satisfactory in two-thirds of the patients, and in only the remaining one-third was a cranial decompression and drainage found necessary.

In the operative treatment of patients having these acute conditions of localized purulent meningitis in whom the cerebrospinal fluid at lumbar puncture is free from bacteria, although it may be turbid from an increased number of cells due to the meningeal irritation, it is most essential that free drainage be afforded. Not only does the vertical subtemporal incision permit a more profuse discharge of the purulent exudate and of the infected cerebrospinal fluid, but this incision is through a clean aseptic area of the skull, and if no purulent exudate of a localized meningitis is found, there is little danger that a purulent meningitis will result from the exploratory opening into the subdural spaces. If, however, the dura is opened through the "dirty" infected field of the mastoid or of the nasal sinuses, even if no purulent meningitis is found, the operation in itself will most probably permit the extension intradurally of the infected process—with the greatest risk to the patient. Besides, if the infective process has extended into the subdural spaces slowly, as it usually does in the course of mastoid and nasal sinus disease, then there is frequently sufficient tissue reaction to permit the surrounding meningitis to "wall off" the infective process and therefore, if an attempt is made to drain the subdural spaces through the infected mastoid or nasal sinuses, the amount of drainage is very much lessened and at times practically nil. If, however, the dura has been torn at the time of the injury or of the preceding operative procedure, then the infective meningeal symptoms will be of a fulminating character and the entire clinical syndrome will be presented within two to four days on account of the absence of this natural barrier of tissue reaction. In these cases, efficient drainage of the purulent exudate may be obtained through the mastoid or nasal sinuses, but there will still be the risk of opening the dura through these infected areas and of not finding a subdural infective process—which would later develop as the result of the operation. In view of these considerations, it is always better surgical judgment in conditions of localized meningitis presenting the signs of becoming diffuse, to drain the subdural spaces through the "clean" subtemporal incision rather than to attempt drainage through the infected mastoid or nasal sinuses; if

a purulent meningitis is revealed by the subtemporal incision, then combined drainage may safely be obtained through both the decompression and the mastoid or nasal sinuses; besides, the possibility of a latent brain abscess in the adjacent temporosphenoidal and frontal lobe can also be excluded through the subtemporal incision, either by exploratory subcortical punctures in the absence of a purulent supracortical exudate associated with a tense protruding cortex, or merely by observing that the brain recedes and pulsates normally following the escape of the cerebrospinal fluid, and in these latter cases it is very improbable that an adjacent cerebral abscess is present.

The following case-histories are reported in outline and very briefly—merely to indicate the character of the intracranial infection and the operative treatment instituted:

CASE I.—Acute purulent meningitis following mastoidectomy. Subtemporal decompression and drainage. Excellent recovery. No. 14—Hillman. 13 years. White. School. U. S. Admitted—September 26, 1015, Polyclinic Hospital. Referred by Doctors Keller and Zeiner. Operation—September 26, 1915. Right subtemporal decompression and drainage. Discharged—November 13, 1915, 46 days after operation.

Family history, negative. Past history: Three weeks ago, after a period of swimming daily in a lake at a Y. M. C. A. camp, patient complained of severe pain in the right ear; pain gradually became worse until two weeks ago, when a profuse purulent discharge from the right ear gave immediate relief. The purulent discharge continued for several days, the mother irrigating the right auditory canal and inserting cotton to prevent the continuous discharge.

Eight days ago, the patient again complained of severe pain not only in the right ear but over the right mastoid area; an examination revealed localized tenderness and a boggy edema over this area; the temperature was 101.8° and the blood count of 12,000 white cells contained 82 per cent. polynuclears. An immediate right mastoidectomy was performed; no extensive involvement of the cells ascertained and a radical operation was not considered advisable. Condition of the patient did not improve markedly following the operation—the temperature remained above 101°, the amount of purulent discharge was slight, and on the fourth day post-operative (4 days ago), the temperature ascended to 103.2° pulse 90, respiration 28, and the patient complained of excruciating headache; extreme restlessness.

Present illness: Three days ago, at two o'clock in the morning, patient suddenly had a convulsive seizure beginning on the left side of the face and then involving the left arm and the left leg and finally the entire body in a typical epileptiform attack. A second similar convulsion occurred within thirty minutes to be followed by a third one in about twenty minutes. These epileptiform spells continued at intervals of only minutes for eight hours, when they ceased for several hours only to return, but less frequently. During the past two days the spells have continued at varying intervals and the patient has become much weaker and mildly delirious.

Examination upon admission, 8 days after mastoidectomy. T. 105°, P. 94, R. 30. Rather stuporous and drowsy. Definite rigidity of the neck almost to a degree of slight opisthotonos. Positive bilateral Kernig test. Pupils: right slightly smaller than left; otherwise negative. Reflexes: patellar very active, but apparently equal; tendency to left Babinski, but very inconstant; abdominal both depressed, left more than right. Fundi-retinal veins enlarged but no edematous obscuration of either optic disk. Lumbar puncture: not over 2 c.c. of turbid and cloudy cerebospinal fluid removed under a definitely increased pressure; bacteriologic report (Doctor Jeffries)—"large number of cells (over 160 per c.mm.), but no bacteria observed in the stained specimen." The culture was later reported to be negative. *Treatment.* The absence of bacteria in the cerebrospinal fluid at lumbar puncture made possible the diagnosis of a localized meningitis or at least a severe meningeal irritation and meningismus, and therefore an immediate subtemporal decompression and drainage was advised and performed. The localizing Jacksonian character of the convulsions was very significant—three spells occurring while the patient was being prepared for the operation. *Operation,* 8 days after mastoidectomy. Right subtemporal decompression and drainage; usual vertical incision, bone removed and no complications. Dura was under definite tension and upon incising it, cloudy cerebrospinal fluid spurted to a height of almost 2 inches. The dural opening was enlarged, exposing a "wet" edematous cortex and in the sulci about the supracortical vessels was a purulent exudate in the arachnoid spaces. A stained specimen and a culture of the exudate were later reported "streptococci." From the lower angle of the incision and apparently coming from the middle fossa beneath the right temporosphenoidal lobe were extruded several drops of frank pus (streptococci). The cerebral cortex protruded, but the rapid escape of cerebrospinal fluid quickly permitted normal pulsation to occur. Two drains of rubber tissue were inserted beneath the dura at the upper and lower angles of the incision. Usual closure with catgut. Duration, 40 minutes. The mastoid dressing was later removed by Doctor Keller and the area was carefully inspected for a purulent extradural focus but with negative results; the usual mastoid dressing was reapplied. *Post operative notes.* Within four hours the temperature dropped 2.5 degrees, the general condition of the patient improved, and 12 hours later the restless delirium had disappeared together with a lessening of the rigidity of the neck. Only three slight convulsive seizures occurred after the operation and within the first 24 hours, but none since. Profuse purulent discharge from the lower angle of the decompression incision continued for 48 hours, when it gradually lessened to a discharge of not more than one drahm for over one month—the temperature remaining around 100° and the respiration 86. The drains were finally removed on the 33rd day post-operative and the incision healed completely. The mastoid area granulated without complication so that the patient was discharged from the hospital on the 46th day post-operative; the decompression area was slightly depressed and the only impairment to be elicited by the tests was an impairment of hearing of the right ear. The patient made an uneventful recovery of his former normal health; no convulsions and no mental, emotional, or physical sequelæ with the exception of the deafness of the right ear resulting from the otitic infection. Last examination, April 27, 1921, 5½ years after operation. No complaints except the right auditory impairment. Patient has become a strong, husky youth of 19 years, a member of the state militia and is studying engineering. Not a single convulsion since the day of the drainage operation in 1915. Pupils, negative. Reflexes negative. Fundi, negative. No mental or physical impairment other than the deafness of the right ear.

Remarks.—The period of time elapsing since the occurrence of the acute purulent meningitis makes the danger of brain abscess formation most remote in this patient, and I am of the opinion that this patient can be considered as "cured."

If the operation of subtemporal drainage in this patient had been delayed until bacteria were found in the cerebrospinal fluid at lumbar puncture, then the positive diagnosis of a diffuse purulent cerebrospinal meningitis would havs been possible and naturally the patient would have been considered beyond all hope and any drainage operation entirely futile. But as in this case, although the cerebrospinal fluid was turbid and cloudy and the clinical signs of rigidity of the neck, bilateral Kernig, and high temperature formed a syndrome frequently indicative of a diffuse cerebrospinal meningitis, the absence of demonstrable bacteria in the cerebrospinal fluid at lumbar puncture permitted the condition to be considered as one of localized meningitis

with the signs of diffuse meningeal irritation, and therefore the operation of subtemporal decompression and drainage was immediately indicated. In these cases, to wait until bacteria present themselves in the cerebrospinal fluid at lumbar puncture, merely makes possible a high mortality and any surgical procedure at this late date becomes discredited and properly so, being similar to cranial operations performed upon patients having brain injuries with high intracranial pressure after the stage of medullary (bulbar) edema has developed. These patients all die, operation or no operation; these terminal conditions fortunately can usually be anticipated in the treatment and thus the patient be afforded a chance of recovery.

Even should the patient recover with life following an acute diffuse purulent cerebrospinal meningitis—and it rarely occurs—then it is very doubtful that the recovery of the former normality is possible owing to the great probability of a permanent destruction of some of the cellular nerve structures. From this standpoint alone, therefore, it is imperative that the infective process be rationally treated and drained early before the localized condition becomes one of diffuse character and practically hopeless.

Just as the attempt of operative drainage of suspected brain abscess is always an exploratory procedure, the dural opening for the drainage of a suspected purulent meningitis should be through the "clean" subtemporal area and not through the "dirty" infected field of the mastoid, sinus, or compound fracture of the skull; for if the purulent process is not present or at least is not located, then there is little or no danger of introducing subdurally infective organisms and thus producing a purulent meningitis or abscess formation—as would most probably occur following an attempted drainage through the infected mastoid, sinus, or fracture area.

The ipsolateral constriction of the right pupil was indicative of an irritative lesion of the right cerebral cortex and together with the depressed left abdominal reflexes, the inconstant left Babinski and the convulsive seizures beginning on the left side—these clinical signs facilitated the intracranial localization.

It is important not to remove more than 1 or 2 c.c. of cerebrospinal fluid at lumbar puncture in these patients, as a more profuse spinal drainage might hasten the extension intraspinally of the infection into a diffuse process. One c.c. of cerebrospinal fluid is sufficient for all of the bacteriologic tests and if an estimate of the pressure is also desired, as in conditions of suspected intracranial tumor, hemorrhage, or hydrocephalus, then the spinal manometer may be safely used, and not even 1 c.c. of the cerebrospinal fluid be permitted to escape. Lumbar puncture, when properly performed, is without risk to the patient.

CASE II.—Acute purulent meningitis (streptococci) following mastoidectomy. Subtemporal decompression and drainage. Excellent recovery. No. 31.—John. 48 years. White. Married. Merchant. U. S. Admitted—November 5, 1920. Nilsen Sanitarium. Referred by Doctors Jarecky and Kellogg. Operation—December 1, 1920. Right subtemporal decompression and drainage. Discharged—December 20, 1920, 19 days after operation.

Family history, negative. Past history, negative.

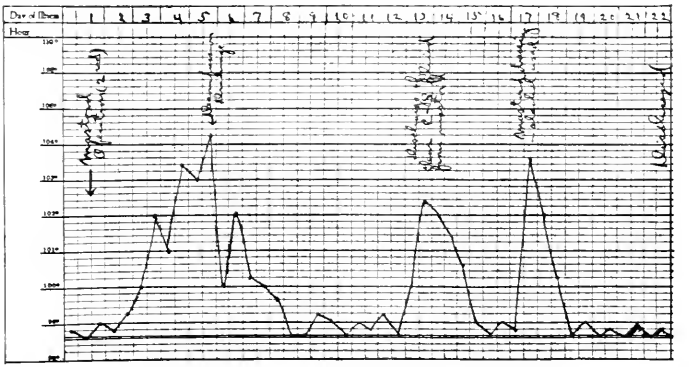
Present illness. During the first week of September, 1920 (almost three months before the present admission to the hospital), patient complained of severe pain over the right parietal area and in the right ear. A brief summary of the case-history follows: September 7, 1920—Incision of right tympnic membrane. Pus escaped. October 22, 1920—Opening in right tympanic membrane enlarged for drainage. November 6, 1920—First mastoid operation; extensive bony necrosis; pus. November 27, 1920—Second mastoid operation; small area of dura exposed. Upon the day following this operation, the temperature began to ascend from 99° to 102°, and on the third day the temperature reached 104.2°. A lumbar puncture at three P. M. revealed turbid cerebrospinal fluid, but no bacteria were found in the stained specimens. Consultation with Doctors Jarecky, Stephens, and Kellogg on November 30, 1920, at 8 P. M. T. 104.2°, P. 100, R. 22. Conscious; very restless and with anxious facies; complains of severe pain over right parietal area. Definite rigidity of the neck; positive bilateral Kernig test. Pupils—equal and react to light normally; no nystagmus. No ocular paralyses. Left lower facial muscles possibly weaker than right; left corner of mouth droops and left labio-nasal fold is less marked. No paralyses nor sensory impairments of the extremities ascertained. Reflexes: patellar, active but equal; no Babinski nor ankle clonus; abdominal reflexes, diminished, especially the left. Fundi, retinal veins slightly enlarged but no edematous obscuration of either optic disk. Lumbar puncture: 2 c.c. of cloudy and turbid cerebrospinal fluid carefully removed; cell count, 200 cells per c.mm., but no bacteria observed in the stained specimens; cultures made. Mastoid dressing changed and no local complication ascertained.

Treatment: The diagnosis of meningeal irritation could at least be made with a most probable localized meningitis as being the underlying cause following the right mastoid infection. The danger of the localized meningitis becoming a diffuse one was so imminent that a delay of even hours would be a most serious mistake of judgment, so that an immediate right subtemporal decompression and drainage was advised in the hope that efficient drainage being afforded to the localized meningitis would prevent its extension into a diffuse process. *Operation,* December 1, 1920 (2 A. M.). Right subtemporal decompression and drainage: usual vertical incision, bone removed, and no complications. Dura tense; upon excising it, turbid cerebrospinal fluid freely escaped, exposing a swollen edematous cortex; in the sulci about the supracortical veins was a purulent exudate extending upward over the right temporosphenoidal lobe of the mastoid area and beyond the Sylvian fissure. Cultures were later reported "streptococci." A large quantity of cloudy cerebrospinal fluid escaped, permitting the bulging cortex to recede and to pulsate normally at the end of the operation. No exploratory punctures, in search of a possible brain abscess, were made. Usual closure with two drains of rubber tissue inserted within the dura and beneath the temporosphenoidal lobe at the base. Duration, 45 minutes. The mastoid area was now thoroughly examined by Doctor Jarecky in search of a purulent focus for the meningeal involvement, but no complication was ascertained.

Postoperative notes. Within six hours, the temperature had fallen four degrees to 99.2°, the pulse to 90, and the respiration to 20; twelve hours later, the temperature had risen to 102.4°, but the pulse did not exceed 92; the rigidity of the neck could not be elicited at this time and the Kernig tests were negative. A dressing of the subtemporal drainage incision now revealed a profuse purulent discharge ("streptococci") and this free escape of the purulent exudate continued for two days when it gradually lessened as the temperature fell, so that on the third day after the operation the temperature reached the normal of 98.6 (Vide clinical chart). The decompression incision closed on the fifth day and all sutures were removed on the seventh day post-operative. The hospital residence of nineteen days was uneventful with the exception that on the ninth day, the temperature rose to 102.4° associated with a slight discharge of clear cerebrospinal fluid through the exposed dura of the mastoid area; twelve hours after another mastoid dressing, however,

the temperature fell to 101.2°. On the following day, the temperature again became normal and remained so until the thirteenth day, when a second sudden rise temperature followed a mastoid dressing in which alcohol was used to cleanse the granulating tissues. At the dressing, several drops of clear cerebrospinal fluid could be observed trickling from the apex of the mastoid area; there was an associated stiffness of the neck and a questionable positive Kernig test. The temperature, however, quickly fell within twenty-four hours to 100° and became normal upon the following day. At discharge from the hospital on the nineteenth day after operation, the patient was in excellent condition and the mastoid area was being filled with healthy granulating tissues. The decompression incision was entirely healed and the operative area was slightly depressed; normal pulsation. Neurologic examination, negative. After several weeks at home, the patient had no complaints and the mastoid area was completely healed.

Last examination. June 6, 1921—six months after operation. Patient has just returned from a vacation of several weeks and is now back at work—"as well as ever"; no complaints; mastoid area entirely healed. Decompression area depressed and pulsates normally.



Neurological examination, negative; reflexes active but equal. Fundi negative.

Remarks.—The almost immediate improvement following the efficient drainage afforded by the subtemporal incision is clearly illustrated by the clinical chart of this patient; as the profuse purulent exudate escaped, the temperature and pulse fell to normal within three days, while the rigidity of the neck, the positive Kernig, and the other signs of acute meningeal irritation entirely disappeared. The general improvement of the patient was correspondingly marked, so that at the time of his discharge from the hospital on the nineteenth day after operation, he could be considered a well man.

The two complications during the hospital convalescence were undoubtedly due to a mild localized meningeal irritation resulting from a dural erosion permitting cerebrospinal fluid to escape; fortunately, no intradural infection occurred. The immediate return, however, of the rigidity of the neck and of the positive Kernig indicated the irritability of the meninges and their sentiveness to stimuli; and thus they are early and most delicate signs of meningeal involvement.

If the operation of drainage had been delayed for some hours in order to obtain the report of a culture of the cerebrospinal fluid and thus be doubly certain that no bacteria were present, then the opportunity of affording this patient a definite chance of recovery might have been lost, for once a diffuse purulent meningitis is demonstrated by the presence of bacteria in the cerebrospinal fluid at lumbar puncture, then it is too late, operation or no operation.

No attempt was made during the operation to ascertain the presence of a possible brain abscess for the following reasons: not only was the supracortical purulent exudate sufficient to account for all of the symptoms and signs, but to pass an exploratory puncture needle through this infective process into the cerebral tissues would, in the absence of a subcortical abscess, certainly have produced at least one brain abscess; then again, no abscess formation was considered probable in this patient because the cortex receded and pulsated normally following the escape of the turbid cerebrospinal fluid. It would have been most unusual for a true brain abscess to have also been present, as in such cases the cortex remains tense and bulging and is frequently of the "dry" type. Another advantage, therefore, of the subtemporal exposure over the comparatively "blind" method of approach through the mastoid or nasal sinuses is well illustrated in this method of operative treatment of these most serious conditions.

20 WEST EIGHTIETH STREET

SPEECH.

BY EDWARD D. FISHER, M.D.,

NEW YORK,

PROFESSOR OF MENTAL AND NERVOUS DISEASES, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

SPEECH *per se* is entirely a mental process. It must necessarily be acquired by the sense of hearing especially, and later sight and touch, as for a full understanding of language, the thing thought of must be fully known. All language comes through the senses. In order to make this useful to ourselves and to express it to others, there must be evolved some symbols, and this represents speech.

Speech is therefore internal; articulation is not necessary to its existence, as seen in the deaf and dumb. Articulation, however, is the external manifestation of speech and has its motor center, *i.e.* the left third frontal lobe, just as the hand has its center.

Speech is the register of thought, the index of its quality; words themselves are no true index or estimates of the quality of language (speech) or thought. It is not in the number of words in the

vocabulary that the true value of speech or thought can be weighed. The child, before it has acquired language, is incapable of thought. The animals do not think. This training for special work is accomplished by repeated impressions, hardly perceptions, carried to the brain, leading to a reflex response which finally becomes automatic. Articulation is, therefore, simply the mechanical manifestation in outward form of the true internal speech or thought —for, in other words, speech is thought.

It is hard to conceive of a special center of speech. It is easy, however, to conceive of special centers for the perception of the elements which make up the various elements of speech, as for instance, the center for the spoken word, that for the written word, and that for gesture. The correlation of these by association, together with many other centers which receive the knowledge of things to be spoken of and its relation to other things, is probably lodged in some so-called higher center which has not as yet been localized, as it has been for the various elements which make up speech and which must remain intact if there is to be any outward manifestation of speech.

To deny the existence of centers of the various components of speech seems erroneous. Constant examples of lessons of the left hemisphere, in given areas showing themselves with rare exception in definite clinical failure of certain elements of speech, as word deafness and blindness and motor failure of expression, cannot be set aside; lesions in other parts of the brain of serious character produce no such disturbance nor do even lesions of any kind of the opposite side of the brain, corresponding to what we call sensory or motor centers of speech.

Marie, it seems to me, confuses internal and external speech—the latter not truly representing speech but merely its manifestation to others, that is not to the individual. We can thus comprehend the possibility of the retention of full intelligence and thought in an individual who is speechless as far as outward expression is concerned. The fact that the deaf, dumb, and even the blind, when all these avenues for the acquisition of speech are absent from birth, can in the truest sense acquire speech through touch is convincing to me of the wholly internal nature of speech.

The mechanism of speech soon becomes automatic; though even appropriate combination of action of the lips and tongue in uttering a word is lost sight of, thought or internal speech goes on, regardless of the mechanism. This is indeed no different from the artist at the piano, especially of the improvisor, the mechanism of the execution must be forgotten. It has indeed taken years of study and repetition for its acquisition, but it must be relegated to the subconscious if the higher elements which make of the master in execution, *i.e.*, feeling and emotion and thought, are to be manifested. No telegrapher, if he thinks of his motor expression, can be rapid, for as soon as that obtrudes itself on his consciousness he becomes conscious of the mechanical execution and places himself on the same plane as the beginner trying to acquire the art. All great orators follow out unconsciously the same process; thoughts come quickly, intelligence tries to make itself manifest in speech, but if the consciousness of the mechanism comes too prominently to the individual consciousness, failure of expression results. Some are born with centers that need very little stimulation for development.

Speech is really thought; without the former it is difficult to understand the existence of the latter. Thought could indeed be manifested by acts, such as, for instance, the building of a bridge, a house, etc., but in human experience such a thing has not occurred.

Speech is, however, in its entity, purely internal, *i.e.* it can and does exist primarily in the brain as thought; its expression in speech or words is only the outward sign, that is the mechanism by which it shows itself to others; but after all it must be internal in its true essence, and if this internal speech remains, the intelligence of the individual may be unimpaired although he does not possess the means to manifest it.

6 East Fifty-second Street

THE TREATMENT OF EPILEPSY.

BASED ON RECORDS OF FIFTY-EIGHT CASES.*

By I. S. WECHSLER, M.D.,

NEW YORK

ASSOCIATE IN NEUROLOGY, COLUMBIA UNIVERSITY, NEW YORK; ASSOCIATE ATTENDING NEUROLOGIST, MONTEFIORE HOSPITAL; ADJUNCT ATTENDING NEUROLOGIST, MT. SINAI HOSPITAL, NEW YORK.

From time to time various reports on the treatment of epilepsy emanate from different sources, some observers extrolling the virtues of one drug, others rhapsodizing over the merits of another. At times specific methods receive their acclaim for a while, at others, praise is bestowed on a special form of treatment to bear out some pet theory. Occasionally an iconoclast pillories all methods to prove that there is no treatment. The opinions, no doubt, are put forth in all sincerity and frequently bear the stamp of conviction; but the very divergence of opinion testifies rather significantly to our want of understanding of the nature and causes of epilepsy and points even more significantly perhaps to the absence of any real, not to say specific, treatment.

The causes of this divergence of opinion are perhaps not difficult to find and may rest on the want of uniformity in the conception of the symptom-complex and the choice of patients. It probably makes some difference whether one treats hospital and institutional patients or those who come to the clinic; or whether one can influence the environment and control the diets and general hygiene of his patients. The type of epilepsy, whether it be grand or petit mal or whether it represents a psychic equivalent, undoubtedly influences the result of the treatment. The severity and duration of the disease, the sex, the age of onset, the occupation, and other possible contributory factors very likely affect the ultimate result. In view of the great variety of circumstances attending an apparently uniform condition it is not strange that so many different results are obtained by various observers employing different drugs or methods, or that the results vary at different times.

A more fundamental cause for the difference in results lies in the fact that we do not always bear in

*From the Department of Neurology, Vanderbilt Clinic, New York.

mind that epilepsy, that is, so-called essential, idiopathic epilepsy, probably has a number of causes and that it is not a disease. We do not even begin to understand the fundamental metabolic processes probably underlying the condition. It may be presumptuous to repeat so elementary a statement but the trite fact is that epilepsy is a symptom, a symptom-complex perhaps, but only a symptom of an underlying condition which is ill-understood or possibly not understood at all. The convulsion may be a sign of cortical irritability, and probably is, but this statement does not even begin to answer the question of causation, possibly begs the whole of it and certainly does not make of epilepsy more than a symptom. Emphasis on this point is necessary not to impress a fact which is so wellknown to everybody, but to explain the difference in the results of treatment. If essential epilepsy is a symptom-complex then the treatment, any treatment, is more or less symptomatic and must remain such until we know more about its etiology and pathology.

It is not the object of this paper to enter into a discussion of the very wide subject of epilepsy, to define the symptom-complex, to investigate its etiology, or even to venture positive views on the merits of some forms of treatment to the exclusion of others. It is merely an attempt to give the results of the treatment of fifty-eight patients who have been observed for varying lengths of time at the Vanderbilt Clinic. A few suggestions may be put forth here and there and possibly some conclusions drawn afterward.

Some of the patients have been under observation for several months, a great many of them for a year or more, and a few have been regular visitors to the clinic for a decade or two. In the past year and a half or longer I have personally observed all the patients coming to the first division of the Vanderbilt Clinic, making it a point to see those suffering from epilepsy regularly once in two weeks. Those who did not respond to treatment were asked to report once a week, while others who did well were seen only once a month.

The number of cases of epilepsy herein reported represents but a portion of those who are treated at the clinic. Only so-called true, idiopathic cases are included in this study. Every attempt, of course, was made in each instance to exclude possible appreciable causes such as lues, trauma (resulting either in general or focal manifestations), sequelæ of recent encephalitis, etc., and even though in many instances the ultimate pictures, that is the convulsive phenomena, might be regarded as true epilepsy they were not included in this study. Record of the treatment of each patient, as well as record of the number of attacks was kept throughout the period of attendance at the clinic.

In most cases attempt was made to regulate the diet or even eliminate articles of food commonly held objectionable in epilepsy, to correct disturbances of the gastrointestinal tract, to outline general hygienic measures, and even to suggest occupational changes. It may be pointed out that the clinic or office patient cannot be controlled as well as the institutional one so that many orders given by the therapist frequently are either poorly carried out or not at all. This is particularly true, for instance, in cases where one outlines a salt-free diet. The inability or unwillingness on the part of the patient to cooperate in the management very likely vitiates the results of treatment to some extent, but this is something which every therapist has to reckon with in the treatment of home patients. It is perhaps worth mentioning that although epileptic attacks usually tend to increase in frequency if the patient remains untreated, not infrequently they cease spontaneously—a fact which has been observed by every neurologist. In such cases one may attribute to a drug an efficacy which it does not possess; prolonged observation, however, usually serves to eliminate this possible source of error.

Luminal.—In recent years luminal has attained a preeminent place in the treatment of epilepsy and has practically crowded out all other drugs and methods. The glowing reports one reads from time to time lead one to think that a specific has at last been discovered. At the risk of becoming a heretic I may say that my experience does not (in a great measure) anywhere near bear out the reports of the wonderful results claimed for it. That the drug does reduce the number of convulsions and at times even stops them the records of some of my cases will show, but that it is the only drug or even the best drug in all cases is not borne out by my experience. Claims have been made that it is a dangerous drug, this I do not know; but that it has disadvantages one may safely say. That it fails in very many cases one may also assert. I have even seen it change grand into petit mal attacks.

Of the fifty-eight patients, all of whom received luminal for varying lengths of time, in doses of $\frac{3}{4}$ to $1\frac{1}{2}$ grains one to three times a day, eighteen may be said to have had their attacks stopped by the drug. A few case records will illustrate its effects.

Case I.—W. T., male, age 35, came to the clinic March 12, 1920, having had epileptic attacks for two years. They had gradually increased in frequency—one per month—until just before coming to the clinic he had had six in one week. Bromides stopped them for three months. Luminal, gr. $\frac{3}{4}$ was then given three times daily, and he has had no attacks to date.

Case II.—C. S., male, age 30, came to the clinic in February, 1920. He had had regularly one attack a month since the age of fourteen. He was put on luminal and he has had no attacks to this day.

Case III.—C. S., female, age 18, came to the clinic in August, 1919. She had had almost daily attacks since 1916. She was given bromides and the attacks were reduced to one in two weeks. Luminal was given and they stopped for six months. Owing to the fact that we could not get luminal she was given dial ciba; the attacks returned. Luminal was then tried again in $\frac{3}{4}$ grain doses with no effect. The dose was increased to $1\frac{1}{2}$ grains and the attacks have stopped entirely.

Case IV.—J. V., male, age 29, came to the clinic February, 1919. He had attacks every month or two for the preceding year and a half. Luminal stopped them.

Case V.—A. K., female, age 15, came to the clinic February, 1920. She used to have one attack in three or four weeks since 1916. She received one grain of luminal twice daily and has had no attacks since.

Without reporting the rest of the cases it may be seen that luminal can keep convulsions in abeyance so long as its administration is kept up. No sooner, however, is the drug stopped than the attacks return. Many patients claim that they feel "dopey"

while taking luminal. The drug has little or no effect on petit mal attacks. In many cases it has no effect at all. A few records will illustrate this point.

CASE VI.—F. S., male, age 7, came to the clinic July, 1919. Has had daily attacks since February, 1919. He received luminal in increasingly large doses, but it had no effect.

CASE VII.—H. B., male, came to the clinic in April, 1920, with the history of seizures once a week or oftener. Luminal reduced the attacks to one a month or one in two months up to December, 1920; then, despite treatment, they returned at the rate of one a week. (This patient was subsequently given bromides and the attacks have ceased to date.)

CASE VIII.—G. B., female, age 21, came to the clinic in December, 1920. Has had attacks since 1916; they gradually became more frequent so that they came on every few weeks, usually at night, and occasionally up to a dozen at a time. Luminal in doses up to a grain and a half had no effect.

In one or two instances I have seen luminal aggravate the condition. Although it has been repeatedly asserted, and my experience partly bears this out, that luminal does not effect petit mal attacks, the following case may be cited to show that it sometimes does; but it apparently did this at the expense of the grand mal attacks.

CASE IX.—M. L., male, age 19, came to the clinic in August, 1920. He had had grand mal attacks at the rate of one a month since 1916, and petit mals several times daily during the intervals. Upon receiving luminal the grand mals increased in frequency while the petit mals were reduced to an occasional one every few days. (This patient subsequently received bromides and both the grand and petit mals were reduced in frequency, though not stopped altogether.)

It may be seen, therefore, that while luminal is a very valuable drug it is not a specific, and, while it should be tried in all cases, one should not hesitate to discard it for some other method of treatment, particularly for the well-tried bromides.

The Bromides.—It is perhaps a little too late in the day to hold a brief for the bromides, all the more as they have fallen into such disrepute among the neurologists. But despite their disadvantages, such as general inefficacy in many cases, objectionable rashes, possible mental deterioration from prolonged use, gastric upsets, etc., the bromides are at times the only drugs that have any effect on epilepsy. It is not necessary to quote too many cases which showed good results nor the instances which showed failures, but a few reports may be given to remind us that the bromides still have a place in epilepsy.

CASE X.—J. O., male, age 46, came to the clinic in October, 1919. He had had attacks every two weeks since 1913. Bromides stopped them, cessation of treatment resulted in their return and resumption again stopped them. Continued use of the bromides has caused their cessation to date.

CASE XI.—J. R., male, age 30, came to the clinic in July, 1920. He had had attacks at the rate of one a week up to four or five a day since 1908. He received bromides and the attacks ceased. Treatment was changed to luminal just to see its effect, and, while he did not have any attacks, he became cross and "ugly" in temper so that the bromides have again been resumed and continued to date.

CASE XII.—G. S., male, age 53, has been coming to the clinic, more or less irregularly for twenty-five years. The attacks began when he was twenty-eight years old and would come on at times as often as three a day. They stop whenever he takes bromides. He refuses to try any other treatment. The last attack was in 1916 when he did not take his salty medicine; since then he has not failed to take it daily.

In many cases I have tried both bromides and luminal with good results where neither alone seemed to have any effect. In other cases neither the one nor the other drug nor both in combination had the slightest effect—which illustrates once more that failure is often the reward of the treatment of symptoms whose etiology is unknown. Curiously enough a special drug may sometimes help where well-tried remedies do not. In the following instance we just stumbled over the remedy.

CASE XIII.—A. K., male, age 55, came to the clinic early in 1918. He had had severe attacks, two or three a week, since 1913. He was treated with bromides, dial ciba and luminal with very little improvement. He was put on sulfonal, gr. v, t. i. d. and he has had no attack to date. Very rarely he has mild petit mal seizures.

A drug which we have frequently used at the Vanderbilt Clinic during the war days when luminal could not be obtained was dial ciba. This often had an effect similar to luminal, though it was less steady. We still use it occasionally when we run short of the more efficacious drug, but in general we have discarded it for its rival. I merely mention it because it has shown some results and is worth trying on occasion.

The Endocrines.—Perhaps in no branch of medicine (psychoanalysis alone excepted) is the battle so bloody as that waged on the field of the internal secretions. Spectacular successes are claimed by combatants in one camp only to be met by shafts of ridicule from the ranks of their opponents. Results are frequently proclaimed by some men, which honest observers cannot substantiate, and the accusation is then made that the imagination and not the fact is responsible for the vaunted cures. There has even been a little acrimony injected in the uncomplimentary debate. Possibly one need not wonder at these contradictory statements, particularly in the case of epilepsy, when one considers how few are the facts we can as yet bring to bear both on the study of endocrines and the epilepsies.

While it may safely be said that the successes claimed in the treatment of epilepsy with the endocrines are somewhat exaggerated, it is shutting one's eyes to facts to say that no good results have followed their use. Indeed I have personally seen on one or two occasions such remarkable results that I was tempted to use the various products of the glands of internal secretions in many cases of epilepsy. Unfortunately I could not duplicate the results. This may be due to lack of appreciation of certain indications or to some uncontrollable factors. That some of the epilepsies have something to do with the glands of internal secretion may be inferred if we but reflect on how frequently the disease begins at puberty. In young women it is not uncommonly accompanied by anomalies of menstruation. It may be worth while to cite a few cases merely to illustrate the use of the endocrines. I shall not cite the numerous instances in which I obtained no results at all.

CASE XIV.—G. S., male, age 36, was first seen in March, 1919. Attacks began in 1913, were rare at first, one in six months to a year, latterly they became more frequent, about one a month. The patient had a somewhat acromegalic facies. *X*-ray of the sella

showed it to be very large. He had no symptoms of either hypo- or hyperpituitarism. He received whole gland pituitary for several months, but no other medication, and he had no attack to date, covering a period of more than two years.

CASE XV.—S. R., female, age 25, has had attacks regularly twice a month since childhood. She had never menstruated. She was given thyroid extract and told to return in a week. Strange to say she brought the happy news that she had menstruated for the first time in her life. For the next few months she had mild attacks only once a month, at the time of menstruation. Luminal and pituitary extract were then given but the attacks returned and now occur at the rate of one a week to one a month. The menses have continued to come on regularly.

CASE XVI.—P. M., male, age 13, came to the clinic December, 1920. He had psychic euivalents at the rate of about one a week. He looked dyspituitary and *x*-ray of the sella showed it to be very small. He was given whole gland pituitary. For two and a half months, up to the time he was lost track of, he had no attacks whatsoever.

General Remarks.—It may be hazardous to put forth certain inferences, particularly when one has only impressions and no facts to substantiate his remarks, but one may be allowed to venture them if only to stimulate thought or investigation. From the treatment of many cases I have gained the impression, which almost amounts to a conviction, although I can not prove it, that certain foodstuffs bear a special relation to some of the epilepsies. It has, of course, been known all along that various foods apparently have a deleterious influence in epilepsy, but it seems to me that there is something akin to a sensitization, to a reaction (anaphylactic?) of the organism to certain proteins or possibly endotoxins, which result in convulsive phenomena. The periodicity of some of the epilepsies may point in that direction. In a few instances I have been told by patients that certain diets are apt to bring on attacks. One patient definitely attributed his improvement to the fact that he had given up eating eggs and on one occasion when he did eat them (he used to be very fond of them and ate many at a time), he paid for his heedlessness with a convulsion. In this connection we may refer to the partial, though in some instances very significant success recently reported by Dr. Geyelin in the treatment of epilepsy by means of starvation, although his results pointed to some correlation between the number of convulsions and the height of the induced acidosis.

I was also impressed with the comparative absence of mental deterioration in the great majority of the patients. This is particularly noteworthy because many of them had had the disease for years and years and had been taking both bromides and luminal, which are said to accelerate the deterioration. Many patients, too, had very severe and very frequent convulsions and yet showed comparatively little deterioration. One explanation, of course, may lie in the fact that the more severely mentally affected find their way into institutions. Not a few of the patients coming to the clinic are able to continue at their occupations and many who do not fail not so much because of their inability but because they are not tolerated by the people around them. While there is undoubtedly an epileptic mentality which reacts in a special way to the environment, it is a question of how much society and the environment contribute to the shaping of that special mental attitude. So also the irritability of the patients may be aggravated by outside causes, although it is a well known fact that both the bromides and luminal frequently increase it when they stop the convulsions and that the irritability ceases with the explosion.

Conclusions.—Although few of the above observations and the conclusions drawn from them are altogether novel they may serve to reemphasize the common knowledge that, whereas there are treatments for epilepsy, there is no real treatment. Further, that no drug can be said to be specific if for no other reason than that essential epilepsy is not a disease, but a symptom-complex of possibly numerous unknown underlying conditions. So too, it may be observed that any one of the wellknown methods of treatment, however empiric, may at first help to reduce the number of seizures. Sometimes a drug will act beneficially for a time, then cease to have an effect; the substitution of another drug may then bring about renewed amelioration. Success in treatment frequently results only from persistent effort, and if one drug after another does not help it may be wise to combine several of them to obtain desired results. In some cases at times, gradually increasing doses of the same drug may control the seizures when the smaller doses do not. This is particularly true of luminal, which frequently fails if administered in small quantities and succeeds in larger ones. Finally, there are numerous patients who do not respond to any treatment or combination of treatments even if fortified by rigid dietetic and hygienic regulations. It is an extremely humiliating confession to make that many epileptics tax the patience and try the ingenuity of the most persistent therapist, but it is worth making if it will but serve to remind that all the knowledge as yet learned of epilepsy lies in its clinical manifestations.

1291 MADISON AVENUE.

SPECIFIC TREATMENT OF DERMATITIS VENENATA (RHUS TOXICODENDRON).

PRELIMINARY REPORT.

BY ARTHUR SAYER, B.S., M.D.

NEW YORK.

CHIEF OF CLINIC IN DERMATOLOGY AND SYPHILIS, MT. SINAI DISPENSARY.

THE poison oak plant (poison ivy)* is widely distributed throughout North America. It is an uncultivated trailing plant, which grows in our parks, woods, and along the highways. Every summer many persons are inadvertently exposed to this plant, with a resulting cutaneous inflammatory reaction of the parts which have come in contact with it. Some people are quite immune to poison ivy, and even intimate contact with it will not produce any inflammation of their skin. Most people, however, are susceptible, and the merest chance contacts cause an intensely itching local cutaneous inflammation.

The cause of the dermatitis is a non-volatile oily

*According to the U. S. Pharmacopia, poison oak is synonymous with poison ivy (Rhus toxicodendron), except on the western coast where the poison oak plant is of a somewhat different species (Rhus diversiloba).

substance[1] derived from the leaves and berries of the plant. This oily substance is irritating to the skin, and produces locally an erythema and edema with numerous small aggregated vesicles which tend to exudation. Many of the vesicles tend to linear formation, due to the fact that the contact was a scratch from the plant. The lesions are extremely itching and burning—most patients seek relief solely on account of the severity of these subjective symptoms. The self-scratchings of the patient often result in secondary infection of the vesicles, due to the pyogenic organisms thereby introduced into them. Also, the irritating substance being non-volatile, it may be spread by the patient's hands from one part of the body to another. We therefore often see a typical rhus dermatitis on parts (external genitals, face) which have not been in actual contact with the plant.

Many remedies have been suggested for the relief of the condition. Recently McNair has published an excellent article in which an extensive historical bibliography is given.[2] Physicians and even the laity employ various measures for which they claim good results. The diversity of the suggested remedies, however, is sufficient evidence of the non-efficacy of many of them. It is not surprising, therefore, that further studies are being made for the discovery of a remedy which will promise uniformly good results.

Of all various local measures advocated, the following has proven its merit in numerous instances, and is employed by most dermatologists of my acquaintance: (1) Brisk use of soap and warm water with a brush on the affected parts at the onset of the treatment—to break up the vesicles as much as possible. (2) Follow with applying a 1-1000 potassium permanganate solution for about five minutes—this will oxidize the poison and prevent its further spread. (3) Then apply Calamine and Zinc lotion locally every two or three hours—this will relieve the itching and tend to dry up the vesicles. Under these measures the patient will usually get complete relief from his itching in about five to seven days, and the lesions will dry up and disappear in about fifteen days. Although this treatment is effective, it is nevertheless somewhat prolonged and requires frequent topical applications (which inconvenience the patient and are also messy) in order to keep the annoying itching and burning under control.

We have recently become interested in the specific treatment of rhus poisoning, on account of the highly complimentary published reports of several physicians who have employed it. These men report highly beneficial effects from the intramuscular injection of the tincture of the offending rhus plant. Strickler[3] reported a series of cases so treated, and recently Alderson and Pruett[4] have reported a series of cases similarly treated with marked benefit to the patients. The writer has tried the treatment on a series of patients suffering from rhus dermatitis, and wishes to submit his opinion of the value of this treatment, based on his experience with this group of cases.

In all of our cases we employed a tincture of *Rhus radicans* (same as *Rhus toxicodendron*) which was prepared from the fluid extract as follows: Fluid extract, two parts; alcohol (95 per cent.), nine parts; water, five parts. The average dose given was 12 minims—some cases receiving 15 minims and others 8 minims, depending on the age of the patient and the severity of the eruption. All of the injections were given into the gluteal muscles, using a needle about 1¾ inches long. The injection is quite painless and can be readily administered even to children. Our patients received no local treatment whatsoever—the effects noted were therefore attributed solely to the injected drug.

There have been no ill effects noted from the employment of the drug per se, other than slight pain at the site of injection for eight to twelve hours. We have given one or more intramuscular injections to seven persons, used as controls, who did not suffer from rhus dermatitis (cases of acne, pediculosis capitis, dermatophytosis, etc.). We have noted no local or general reactions in these controls, following an injection of 12 minims of the drug. These patients complained of no headaches, chills, fever, pruritus, etc., nor was there any evidence of a cutaneous eruption seen in any of them. We therefore feel convinced that a dosage of 12 minims is not excessive and is well within safe limits.

We have noted, however, in some of our rhus cases, the appearance of a blotchy erythematous itching eruption on remote parts of the body within twenty-four to thirty-six hours after the injection. This eruption has somewhat the same characteristics as the primary eruption, and is often difficult to differentiate from it. Alderson and Pruett also noted this eruption in several of their cases, and considered it as due to overdosage. In our opinion this phenomenon is not so much a matter of overdosage as it is of interaction of the antibodies formed from the injection with the rhus toxin which may be lying inert on the skin. We know that the intramuscular injection of the tincture Rhus toxicodendron will have no effect on the normal skin—none of our control patients showed any skin eruption nor had any itching as a result of their injection. It is therefore logical to ascribe this sequela as an immunity reaction rather than as a reaction of toxicity.

The following are protocols of our cases:

Case I.—J. S., age 11, presented himself on August 11, 1921, with an eruption of rhus dermatitis on the extremities and chest, of four days duration. He was given an injection of eight minims of the tincture of rhus radicans intragluteally. The patient returned in two days showing marked improvement—the lesions were drying up and the patient had no itching since the injection.

Case II.—H. S., age 60, presented himself on August 6, 1921, with an eruption of rhus dermatitis on the right buttock and left upper extremity of three days duration. Patient complained severely of itching, and was given an injection of fifteen minims of our tincture intragluteally. Patient returned two days later very much relieved. He informed us that the itching became less soon after the injection, and disappeared entirely the next day. The vesicles are drying up rapidly.

Case III.—F. G., age 20, presented himself on July 30, 1921, with an eruption of rhus dermatitis of four days duration on the forearms, abdomen, and back. He was given an injection of eight minims of our tincture. Patient returned one week later feeling entirely well. He informed us that the itching was relieved within twenty-four hours following the injection, and the lesion began to dry up rapidly. About three days after

the injection, the patient noted an erythematous itching eruption on the thigh, which lasted for about one day and disappeared. He is now entirely well of his trouble.

CASE IV.—M. G., age 15, presented himself on July 21, 1921, with an eruption of rhus dermatitis of six days duration, on the hands and trunk. He was given an injection of fifteen minims of our tincture. Patient returned in five days feeling entirely well. He informed us that about eighteen hours after the injection itching stopped entirely, and the lesions began to dry up.

CASE V.—N. K., age 37, presented himself on July 16, 1921, with a rhus dermatitis of three days duration on the legs and thighs. He was given an injection of fifteen minims of our tincture. He returned in three days feeling somewhat relieved. The lesions were seen to be drying up. He was given another injection of fifteen minims. On returning two days later the patient stated that he was all better—the itching left him entirely several hours after the second injection, and the lesions were rapidly drying up. The patient returned on August 16, 1921, with a new eruption of rhus dermatitis of a few days duration on the buttocks. He had again been exposed to poison ivy. He was given an injection of twelve minims of our tincture. On returning two days later, he informed us that he was much better—the itching having disappeared within six hours after the injection.

CASE VI.—G. H., age 24, presented himself on July 19, 1921, with a rhus dermatitis of five days duration on both legs and feet. He was given an injection of twelve minims of our tincture. On returning two days later he informed us that the itching stopped about ten hours after the injection, and that he was feeling well for about twenty-four hours. At the end of that time the itching returned moderately. He was given an injection of six minims of our tincture. He returned two days later and stated that he was feeling entirely well—the itching left him ten hours after the injection and has not returned since. The lesions are rapidly drying up.

CASE VII.—L. S., age 15, presented himself with a rhus dermatitis of one week's duration on the hands and forearms. He was given an injection of ten minims of our tincture. He returned two days later and informed us that he was considerably improved—the itching was slight and the vesicles are drying up. He was given another injection of ten minims of our tincture which relieved him entirely in a few hours.

CASE VIII.—A. C., age 12, presented herself on July 28, 1921, with a rhus dermatitis of one week duration on her upper and lower extremities. She was given an injection of ten minims of our tincture. She returned two days later and informed us that the itching left her within ten hours after the injection and that she feels entirely well. The lesions are drying up.

CASE IX.—J. S., age 50, presented herself on August 2, 1921, with a rhus dermatitis of one week duration on the right elbow and shoulder. She was given an injection of twelve minims of our tincture. She returned four days later somewhat improved—the itching being less and the lesions drying. She was given another injection of eight minims of our tincture which relieved her itching entirely in a few hours.

CASE X.—C. B., age 5, presented herself on July 12, 1921, with a rhus dermatitis on her hands, forearms, and right knee. She was given an injection of twelve minims of our tincture. She returned two days later and informed us that the itching left her two hours after the injection and has not returned since then.

CASE XI.—P. T., age 7, presented himself on August 9, 1921, with a rhus dermatitis on the face, neck, abdomen, and extremities of two days duration. He was given an injection of eight minims of our tincture. He returned in two days feeling entirely relieved of the itching and the lesions drying up.

CASE XII.—A. U., age 7, presented herself on July 9, 1921, with a rhus dermatitis on the face, chest and upper extremities of one week duration. She was given an injection of twelve minims of our tincture. She returned three days later and informed us that the itching stopped the same day of the injection and the lesions were drying up. About two days later a new erythematous itching eruption appeared on the buttocks. The patient was given a second injection of twelve minims of our tincture. She returned two days later entirely well—no itching and the lesions drying up rapidly.

CASE XIII.—M. C., age 33, presented herself on July 7, 1921, with a rhus dermatitis of three days duration. She was given an injection of fifteen minims of our tincture. She returned in three days and informed us that two hours after the injection her itching left her and that she was free of itching for thirty-six hours. At the end of that time an erythematous eruption began to appear on the chest and forearms which itched her considerably. She was given another injection of fifteen minims of our tincture. She returned two days later feeling no better. There was a new eruption on her chest. She was given another injection of eight minims of our tincture. She returned on August 16 when it was noted that the lesions were drying up and not itching, but new lesions are coming out which itched considerably. She was given another injection of twelve minims. She returned three days later feeling much better. She informed us that following the last injection the itching left her for forty-eight hours, but that the itching is commencing again on her legs. She was given another injection of eight minims. She returned in four days feeling very much better and showing no visible lesions. She complains of occasional pruritis.

CASE XIV.—J. B., age 37, presented herself July 19, 1921, with a rhus dermatitis of one week duration on the trunk and extremities. She was given an injection of fifteen minims of our tincture. She returned two days later and informed us that except for a period of a few hours the itching was unimproved. The lesions were noticed to be drying up. She was given another injection of fifteen minims intragluteally. She returned two days later still complaining of the itching. It was noted that her primary eruption was drying up and not itching, but that there was a secondary eruption erythematovesicular in character on the trunk and thighs which itched considerably. The patient was of a nervous type and it was decided to discontinue the injections. She was given some bromides internally, and a calamine and zinc lotion for external application. She returned in three days very much improved.

CASE XV.—R. F., age 44, presented herself on August 9, 1921, with a rhus dermatitis of four days duration. She was given an injection of ten minims of our tincture. She returned in two days and informed us that she was not any better—the itching was said to be very severe. She was given another injection of twelve minims. She returned two days later still unimproved. She claims that the itching is still severe and that she was unable to sleep. There was no secondary eruption seen. The patient was unwilling to continue further treatment with the injections. She was given a calamine and zinc lotion for local application. The patient returned in three days feeling very much better.

CASE XVI.—T. R., age 46, presented herself on July 14, 1921, with a rhus dermatitis on the lower extremities of ten days duration. She was given an injection of fifteen minims of our tincture. The patient returned in two days. The lesions were drying up, but were still itching. She was given another injection of fifteen minims which relieved her itching in a few hours.

CASE XVII.—D. J., age 18, presented herself on July 14, 1921, with a rhus dermatitis of two days duration, on the face, chest and arms. She was given an injection of fifteen minims of our tincture. She returned in two days and informed us that her itching left her within six hours after the injection and has not returned. The lesions are drying up.

CASE XVIII.—F. R., age 24, presented herself on July 5, 1921, with a rhus dermatitis on the extremities, of one week duration. She was given an injection of fifteen minims of our tincture. She returned five days later feeling somewhat better. She informed us that there was no improvement in the itching for thirty-six hours after the injection and the itching became less after that time. There were a few erythematous itching lesions seen on the right arm and right buttock. She was given another injection of fifteen minims. Patient returned four days later feeling entirely well. The itching left her ten hours after the injection. The lesions are drying up rapidly.

After considerable deliberation, we have arrived at the following conclusions relative to the merits of the specific treatment. We have tried not to be oversanguine, and endeavored to evaluate this treatment on the basis of our clinical experiences. We believe that the results obtained in the majority of our cases warrant the acceptance of this form of treatment as a valuable therapeutic measure in all cases of rhus dermatitis. The simplicity of the required technique, and the marked benefit observed in many of the cases, warrant its routine employment. In some cases (about 25 per cent.) the beneficial results are striking and immediate, the itching being relieved within six hours after the injection. In another 25 per cent. of cases the first injection results in partial relief and a second injection causes total relief from the itching. We may conservatively state that there will be material benefit offered to the patient in about 75 per cent. of cases treated solely by this method. Only occasionally will the dermatitis be apparently uninfluenced by the intramuscular injection of the tincture of the offending rhus plant. We are absolutely certain that there is no harm done in any case by the employment of this form of treatment.

We believe, however, that in all cases this specific treatment should be given in conjunction with the local treatment outlined at the beginning of this article. The combination of the two methods will no doubt result in quicker relief in all cases. In those cases where the itching stops soon after the injection of our tincture, the local treatment can soon be discontinued. In other cases in which the itching takes longer to disappear the Calamine lotion can be used a correspondingly longer time. In the few cases in which the injections are apparently of little benefit, the local treatment itself will give relief.

Further studies should be made on the subject. The question of most effective dosage should be determined. Also the cutaneous reactions noted in some cases should be further investigated. I hope to have the opportunity to investigate these phases of the subject and report them at a later date.*

937 SIMPSON STREET

Kala-Azar in Paris.—Carnot and Libert report the case of a man of thirty with a pseudomalaria—intermittent fever with splenomegaly—in whom splenic puncture revealed the presence of *Leishmania*. The blood was free from the malaria parasite and quinine was inert. The man was cachectic and intravenous emetine did not improve him, the case ending fatally. The patient had fought in the Macedonian campaign and until recently had been in good health, so that the *Leishmania* can evidently remain indefinitely in the body before rousing to activity. This is the first case of the sort to be recorded in France and carries the lesson to puncture the spleen in all obscure conditions in which that organ is enlarged.—*Gazette des Hôpitaux.*

ADENOIDECTOMY IN THE ACUTE EAR CONDITIONS OF CHILDREN.

BY JOHN A. GLASSBURG, M.D.,

NEW YORK.

ASSISTANT ATTENDING LARYNGOLOGIST AND OTOLOGIST, NEW YORK CHILDREN'S CITY HOSPITAL, R. I.; SURGEON, EAR, NOSE AND THROAT, STUYVESANT POLYCLINIC.

THE treatment of inflammatory ear conditions is a problem of drainage. There are three ways in which this drainage can be obtained—one created by nature and two devised by the otologist. Nature's method is the physiological route through the Eustachian tube into the rhinopharynx. The otologist's methods are the improvised routes, either through the tympanic membrane by myringotomy or through the bone by mastoidectomy when paracentesis of the drum proves insufficient. Both of these artificial measures, *i.e.* paracentesis and mastoidectomy, result in external drainage with its sequelæ—running ears, weeks of irrigation with the syringing seances of struggling, crying, and exhaustion, possible furunculosis, eczema, and membrane destruction. In addition paracentesis and mastoidectomy remove only the end results of the suppurative process, leaving the cause untouched, because the etiology of the inflammation is not reached through these measures. The cause of the disease is not in the middle ear or in the mastoid cells, but in the rhinopharynx where the "cold" started. Removal of the source will abort or shorten the infection already present and prevent recurrence. Nature's method on the other hand drains the area involved and if aided by adenoidectomy will eradicate the cause.

In order to fully understand the physiological method of internal drainage, and how to procure it when, because of pathological developments, it is interfered with, it is best to refer to the anatomy of the rhinopharynx. The Eustachian tube, which is the drain pipe of the middle ear is influenced in its physiological function by the location and action of the tympanic and pharyngeal openings. The tympanic opening ordinarily is on the level of the anterior superior quadrant of the drum. At times it may be found somewhat lower, extending even as far down as a point corresponding to the superior border of the inferior quadrant. Rarely, if ever, is it found at the base of the inferior quadrant, where one would expect to find it ordinarily, if gravity were a factor in the drainage. The location of the orifice, therefore, eliminates gravity as a means of drainage through the tympanic opening. The secretions have to be pushed upwards in order to be drained into the pharynx. This is accomplished under normal conditions by the sweeping movement of the cilia of the epithelial lining of the tympanic cavity, the force being directed towards the tubal orifice.

The important orifice that concerns us in reference to aural inflammation is the pharyngeal. The action of this orifice is very peculiar, inasmuch as it has a suction, or pumping influence on the tube. This suction is due to the contractions of the tensor veli palati (sphenosalpingostaphylinus) the levator palati (petrosalpingostaphylinus) the pharyngopalatinus and the salpingopharyngeus muscles. The former two are used in yawning and swallowing,

the latter two are used in deglutition only. The muscles connected with the palate open the tubal end and elevate the soft palate. The pharyngopalatinus opens the orifice when it contracts during the act of swallowing. The salpingopharyngeus runs from the body of the pharyngoplatinus to be inserted into the inferior portion of the tube. This muscle is sometimes known as the third faucial pillar and is of relatively minor importance.

Any interference with these muscles or with the pharyngeal opening will cause obstruction of ventilation and drainage, damming back of the secretions, and consequent aural inflammations. Interference with the muscles is very common as demonstrated by the ferequncy of ear pains in acute tonsillitis. This is due to the swelling of the pharyngopalatinus, which is the posterior pillar of the fauces. The muscle being swollen takes up more space, blocks up the pharyngeal orifice, deranges the ventilation, increases the pressure within the Eustachian tube, and gives rise to the ear symptoms. With the subsidence of the tonsillitis, the muscle returns to its normal volume, the orifice is cleared, the ventilation returns, the intratubal pressure is relieved, and the ear symptoms disappear, the disease taking care of itself.

However, when adenoid tissue is the cause of the orificial obstruction, the pathological course is different. The adenoids have a tendency to proliferate, the obstruction increases and usually remains, the suction action of the tensor veli palati, the levator palati, the pharyngopalatinus, and the salpingopharyngeus is prevented, the damming up of the secretion persists, the epithelial lining of the Eustachian canal is inflamed, the middle ear becomes involved, the tympanic membrane becoming congested bulges and may rupture, or the process may extend further and involve the mastoid cells. The rational physiological method of relieving this condition and removing the cause, is not by opening the drum or the mastoid, but by removing the offending adenoids and reestablishing physiological internal drainage. The removal of the adenoids will not only abort the disease, but by insuring patency of the pharyngeal orifice of the Eustachian tube, prevent recurrences.

The technic of the adenoidectomy is of paramount importance, for the success of the operation depends entirely upon its thoroughness. Adenoidectomy is a comparatively simple procedure, but a complete adenoidectomy, including the tissue around the orifices of the Eustachian tubes, is very rarely accomplished, except by experienced and competent operators. This is readily proved by the frequency of persistent adenoid tissue in the nasopharynx, commonly found after the indiscriminate routine "tonsil and adenoid" operation. The author does not limit himself to any one method in removing the adenoids. The instruments commonly employed are the La Force box adenotome, the plain curet, the finger wrapped in gauze, and the finger nail. The choice of the instrument depends entirely upon the type of case, the amount of adenoid tissue, and the age of the patient. In smaller children and infants no anesthesia is employed. The child is wrapped in a sheet and held tightly by the mother or nurse, the head being retracted. The plain curet followed by the finger with gauze or finger nail usually suffice. In older children general anesthesia is advisable, as it is absolutely necessary in order to get results, to make sure that the lateral pharyngeal walls are cleared, especially the tissues around the fossa of Rosenmüller, which is just behind the Eustachian orifice. It takes very little adenoid tissue to obliterate the patency of the opening which in young children is really nothing more than a slit in the tissue. To insure patency the nasopharyngoscope may be employed. These detailed and careful procedures cannot be performed if the child struggles, and therefore a general anesthetic becomes necessary. A few whiffs of ethyl chloride are usually sufficient, the patient awakening just as the operation is over. The La Force box adenotome is used, it being introduced thrice in succession, once in the median line, once to the right of the median line and once to the left of the median line. The finger wrapped in gauze is then inserted to ascertain whether any adenoids are left near the Eustachian openings. If any are felt, they may be rubbed off with the gauze on the finger, scratched off with the nail, or scrapped off with a small plain curet.

To illustrate the effects of adenoidectomy in the acute ear conditions of children, I will describe a few typical cases:

Case 201.—Jeanette N., an 8 months old baby, had been crying all night. The family physician found nothing the matter with her, but suspecting the ears referred her for examination. The temperature was 103°. Both ear drums were red, the left one bulging. Mastoid tenderness could not be distinguished. The child was wrapped in a sheet, tightly held by the mother, and a few adenoid masses were removed with the plain curet. The gauze-wrapped finger was then inserted and the fossæ well rubbed. The bleeding was profuse. No anesthesia was used. The child slept pretty well that night, awakening only twice and rapidly falling asleep again. The temperature next day was 101°, the bulging was gone, the redness was still present on the left, but entirely absent on the right. The mother did not return for three days, the child having been comfortable, nursing properly, and sleeping well. Examination of the ear drums at this time showed only slight congestion. Two days later the congestion disappeared entirely and the case was discharged as cured.

Case 209.—Philip J., a 3 year old boy had been "cranky" for three days, but since the morning (this was 5 o'clock in the afternoon) was complaining of a shooting pain in the right ear. The history revealed a previous attack the year before, which had required paracentesis, three times. He was then very ill for two weeks, running a varying temperature. At the present time the right ear drum was markedly reddened, all the landmarks were obliterated and tenderness was elicited over the tip of the mastoid. The temperature was 102.4°. The child was anesthetized with ethyl chloride. A La Force box adenotome was used, curetting the median and lateral aspects. Large adenoid masses were removed, particularly from the right side. The finger covered with gauze was introduced and the rhinopharynx was found to be clear. The bleeding was profuse. The next day the child was seen. The temperature was 100°, the mostoid was only slightly tender, the drum was a real red only over Shrapnell's membrane, the rest being of a pinkish hue; the landmarks were still not quite distinguishable. The following day there was a rise in temperature to 102° and paracentesis was considered, but the child complained of no pain or tenderness over the mastoid and the landmarks were visible. The next day the temperature dropped to 99.2° and stayed there until the case was discharged. At the end of the week, all signs of an acute otitis media were gone and the child was discharged as cured.

Case 254.—Ralph P., 4 year old boy, has had frequent attacks of "ear trouble" every winter for three

years. At times the drums would rupture spontaneously and at other times myringotomy would be necessary. At times the right drum would be involved, at other times the left and at still other times both of them would be affected. The mother stated that altogether the child must have had at least a dozen attacks. This time the attack was three day sold, the child not having slept two nights. The hot water bag, hot boric acid irrigation every two hours, leeches, camphorated oil, and phenolglycerin had been used with no appreciable relief of the pain. Upon examination the child appeared acutely ill, his facies was drawn and taut, the cheeks were flushed, he cried and moaned, occasionally emitting a shriek of pain, and presented an acute rhinitis which was probably the focus of his infection. The temperature was 103°. The tonsils were small and could be seen only if pressure was exerted upon them from the outside of the neck. They did not appear diseased. Examination of the ears showed that the left drum had ruptured spontaneously and was draining, but imperfectly. The right drum was markedly congested, the whole of it being red, the landmarks were obliterated, and there was a moderate amount of bulging. No mastoid tenderness. It was after a great amount of persuasion that the mother consented to an adenoidectomy, insisting that the child had never had a sore throat or any "adenoid trouble." The boy was anesthetized. A medium size La Force adenotome was used and each of the three times it was used, it came out packed to the brim with adenoids. The finger covered with gauze removed a few small pieces from the fossa of Rosenmüller and the neighborhood of the Eustachian pharyngeal orifices. The bleeding was profuse. The recovery was remarkable. The next day the temperature dropped to normal, the left ear stopped discharging, the pain was gone, and the congestion of the right drum was diminished.

CASE 281.—Sarah A., a three year old girl, had been complaining for two days of pains in her ears, couldn't sleep the last night, and had a temperature of 102.8°. Examination of the ears showed a slight redness of the right drum and a marked redness of Shrapnell's membrane of the left drum. Mastoid tenderness was marked on the letf side and absent on the right. The child was anesthetized with ethyl chloride. The La Force adenotome was used and large adenoid masses were removed. The bleeding was very profuse. That night the child rested comfortably and offered no complaint in the morning. Examination of the drums showed no redness of Shrapnell's membrane on the right. Mastoid tenderness was still present. The next day the mastoid tenderness was markedly diminished, and the left Shrapnell's membrane was only streaked, not uniformly congested as heretofore. The following day the tenderness over the mastoid disappeared. A slight congestion of Shrapnell's membrane persisted for two weeks with no other associated symptoms. When this congestion finally subsided the case was discharged as cured.

The presentation of these four cases is made because they are characteristic of various types of ear inflammations. The author, however, has performed the adenoidectomy in acute ear conditions in a series of fifty unselected cases. Not all of these cases have shown such uniform good results. Some came too late, suppuration had gone too far, and spontaneous perforation occurred even after the adenoidectomy. This occurred in five cases and was probably due to the great amount of pus present and the consequent increase in pressure, relief of which came too late. In a few cases paracentesis had to be done following the adenoidectomy. This occurred in seven cases and was probably due to the fact that in removing the adenoids some trauma is unavoidably inflicted which in a certain percentage of cases is sufficiently great to cause a temporary swelling of the lips of the pharyngeal orifice of the Eustachian tube and a consequent blocking of the opening. Therefore, in these few cases patency of the canal is not immediately established and paracentesis is necessary.

On the whole the procedure is very satisfactory and it is well to note that all of the adenoidectomies were done while the inflammation was in an acute state, with elevated temperature, congestion, pain, and tenderness and there were absolutely no untoward effects from the operation. The general surgeon does not hesitate to remove an obstructing band, adhesion, or mass in an acute intestinal condition and likewise the otologist should not hesitate to remove an obstructing adenoid mass in an acute ear condition. Although a few cases (five) went to spontaneous perforation and a few (seven) had to be opened up, it surely is gratifying to find that out of this series in which adenoidectomy had been employed not one case developed a real mastoiditis requiring operative intervention and the majority (thirty-eight or seventy-six per cent.) were cured without any paracentesis, sparing the mother and the child the torture of daily irrigations for six weeks or more, keeping the tympanic membrane intact, and preventing chronic running ears, furunculosis, and eczemas.

231 EAST ELEVENTH STREET.

ULCERS OF THE RECTUM.

BY ARTHUR A. LANDSMAN, M.D.,

NEW YORK.

ASSOCIATE SURGEON RECTAL DEPARTMENT POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING RECTAL SURGEON JEWISH MEMORIAL HOSPITAL; DEPUTY SURGEON DISEASES OF THE RECTUM OUT PATIENTS DEPARTMENT, NEW YORK HOSPITAL.

ULCERS of the rectum have a great interest for the physician because of their frequency, variety, and importance in differential diagnosis. The ill effects upon the individual from the secondary symptoms present in certain types, such as the anemia, absorption of toxins into the circulation, and complications arising from interference with bowel function, have further contributed to make this subject one of marked importance to the physician.

The more general and efficient use of proctoscopy has given us more light on this group of cases, and furnished proof that ulcers of the bowels are far more common than was supposed; this need occasion no surprise when we consider the large number of people who suffer from rectal diseases, many of which may sooner or later become associated with some degree of ulceration, ranging from superficial epithelial erosions, to deep destructive lesions of the walls, and from symptoms which cause merely transient annoyance, to permanent impairment of function, and even loss of life.

It may be naturally inferred that when there are such wide differences in effect, there must be differences in the character of the causative agent, and so it has been found. Ulcers of the bowel may be, broadly speaking, simple, when they are the result of innocent causes, unrelated to special bacterial action or particular disease; or specific, when they are of definite bacterial origin, the expression of constitutional disturbance or malignant states.

Simple ulcers occur in the rectum from bruises or tears of the epithelium by stools which are hard, dry, or rough, from the effect of sharp foreign bodies, or as a complication of some local disease

of the organ such as hemorrhoids, fistula, stricture, proctitis, etc. While injuries to the bowel from the sources stated must be quite common, it is fair to presume that they terminate in normal repair except in those cases in which the primary disease is attended by disturbances of nutrition, of which varicosities of the vessels so commonly seen in this region are good examples. Nevertheless, though healing may be sluggish in such circumstances, there is a tendency for the injury to be repaired without interference with the general health or impairment of function, certainly when the local disease receives appropriate treatment.

Not so in the second group, where the problems are different in degree and kind; the local disease is caused by (*a*) a specific organism which produces characteristic changes in the intestine, (*b*) constitutional conditions whose symptoms may appear in the lower bowel, (*c*) some unknown agent which causes changes, at first local, but soon tending to spread to adjacent and remote organs. The lesions are destructive, the complications severe, the course away from spontaneous recovery. In this category belong ulcerations due to amebic or other tropical forms of dysentery, syphilis, tuberculosis, malignancy, and in a milder form ulcers seen in connection with diabetes, uremia, blood diseases, and some severe general infections.

The differentiation of these becomes an important matter for the physician because the laboratory often fails to furnish the evidence necessary to distinguish one from the other. If we are fortunate enough to have an examination of the patient's blood when it still reacts strongly to the complement fixation test, we may be able to base our diagnosis on syphilis, but even then the possibility must always be borne in mind that persons suffering from ulceration of the bowel due to some other cause, may become infected with lues; in amebic dysentery the organisms are sometimes absent from the discharges for weeks or months, or they may after a time be entirely displaced by secondary organisms. Hence the value of the laboratory examination is limited to such cases as show affirmative evidence.

In not a few cases no positive diagnosis of the etiology can be made at the time when the patient presents himself for examination, or later, and his treatment must perforce remain expectant and symptomatic. But certain types of ulceration present sharply contrasting features and fortunately they are frequently the ones in which differential diagnosis is of greatest help. Cases in point are tuberculous ulcers occurring past middle age, in which no primary focus of infection can be located elsewhere, or ulcers in young individuals who happen to be suffering from chronic gastrointestinal catarrh, frequently recurring colds, or other symptoms which might be interpreted as due to tuberculosis, and especially so when they happen to have a tuberculous family history; in these, attention to certain points will frequently clear up all doubt. Broken-down tubercles of the rectum are very rarely single or limited to any very definite regions, but are scattered in various parts of the rectum and other parts of the intestine; they present a shallow, irregular, worm-eaten base, with soft undermined edges and very slightly raised borders, and are, furthermore, characterized by the absence of any marked infiltration. Malignant ulcers, on the other hand, have a tendency to occur singly and spread by direct extension, forming deep excavations with hard edges, raised borders, and a marked degree of infiltration at the base of the ulcer.

Chancres of the rectum are very rare, occur exclusively low down, are single, have an offensive discharge, and are often accompanied by other changes about the anal margin, and enlargement and tenderness of the inguinal glands. Ulcerating lesions of late syphilis, as for example broken down gummata, are apt to be multiple and often accompanied by stricture or evidences of repair. It is characteristic of syphilis of the rectum that it causes a deposit of plastic material in the bowel, increasing its thickness and lessening its caliber. Hence the walls of the rectum may be made out to be firm and inelastic while the lumen is diminished even to the extent of forming stricture, very common in syphilis, especially in the colored race. Moreover, in late syphilis the history and a complete physical examination may afford significant clues.

Amebic ulcers are not limited to the rectum, and in their early stages are generally small, shallow, oval, and circumscribed and covered with a greyish exudate. Later they may become confluent, but the base of the ulcer remains soft, and lacks the infiltration present in malignancy.

Ulcerations which occur in the course of chronic uremia, diabetes, and blood diseases, as they are found in the rectum, are of no essential interest in this connection, as they can neither be distinguished from each other, nor effectively treated, except as it is possible to cure or hold in check the primary disease. But in the other specific forms, the problem of correct and early diagnosis assumes vital importance as it determines the question of treatment and enables us to take timely measures to prevent disability, restore function, and save life.

310 WEST 86TH STREET.

Recoverable Purulent Meningitis.—Schultheiss of Professor Feer's Pediatric Clinic, University of Zurich, reports two cases of this rare sequence. The first case he sums up as follows: Pneumococcus meningitis following an intranasal operation. Treatment consisted of large doses of urotropin followed by five consecutive acts of lumbar puncture. The headache promptly vanished, the mind cleared up, and after each individual puncture the patient ate with relish. The author concludes that the strain of pneumococcus must have been of low virulence, partly because of the slow, insidious onset of the affection and in part by reason of the quick response to treatment. Purulent meningitis almost always sets in violently. The number of organisms was also small and the cultures were poorly developed. The patient was a boy of five years. In the second case, in a boy of seven years, it was a streptococcus meningitis of otogenous origin. Naturally it was an operative case and to the mastoid operation was added a series of lumbar punctures. Of medical treatment the primary resource was injection of streptococcus serum into the spine after puncture. Urotropin was the second course, for it is known that this substance rapidly enters the cerebrospinal fluid. The prognosis in purulent meningitis, almost hopeless as it seems, is yet considerably better than that of tuberculous meningitis, which is practically 100 per cent. fatal. The ages of the patients afforded a slight advantage, for recovery under the age of three or four is more common than in the later years of childhood. Few cases of this lesion are primary.—*Schweizersche medizinische Woehenschrift.*

Medicolegal Notes.

Opinion Evidence Rules Applied in Malpractice Case—Qualification of Medical Expert—Erroneous Reference by Court to Lack of Knowledge of Defendant.—As an expert is not allowed to draw inferences or conclusions of fact from the evidence, his opinion should be exact upon a hypothetical statement of fact. It is the privilege of counsel to assume any state of facts which there is any testimony tending to prove, and to have the opinion of the expert based on the facts assumed. But the testimony should tend to establish the facts embraced in the question. If the hypothetical question is clearly exaggerated and unwarranted by any testimony in the case, an objection to it should be sustained. The form of the hypothetical question, whether it states facts or puts facts hypothetically, or refers to the testimony of witnesses as being true, should be shaped so as to give the witness no occasion or opportunity to decide upon the evidence. Hypothetical questions are clearly improper if they directly seek the opinion of the witness on the merits of the case. In a malpractice case the question whether a physician has in a given case adopted the proper treatment is one in which the opinion of medical men may be received in evidence, and they may state whether in their opinion the treatment was proper or not, whether it was in conformity with the rules and practice of the profession. As the opinion evidence rule is intended to provide against the danger of invasion of the province of the jury, a court should, as far as possible, exclude the inference, conclusion, or judgment of a witness as to the ultimate fact in issue, even though the circumstances presented are such as might warrant a relaxation of the rule excluding opinions but for this circumstance. But the rule is not absolute, for it frequently occurs that the only possible or practicable method of making proof of the fact in issue is by means of opinion evidence. Applying these rules in an action for damages for alleged negligence in setting and treating the bones of plaintiff's wrist, the Oregon Supreme Court holds that it was error to allow the plaintiff to ask his medical witness whether the application of side splints was unskillful and negligent, over the objection of defendant's counsel. The court said: "The distinction between improper treatment and negligent treatment is not as broad as it is vital. Improper treatment by a surgeon might be due to an error in judgment of a skillful surgeon honestly and carefully exercised, and not constitute negligent treatment. Dishman v. N. P. Beneficial Association, 96 Wash. 182, 164 Pac. 943. The opinion of the expert, Dr. Strickland, left little or nothing for the determination of the jury. It was undisputed that two soft pliable wood splints 3½ inches in width were applied by Dr. Knott (the defendant) to plaintiff's wrist, and encircled the same, except for a quarter of an inch on the top and bottom, as Mrs. Lehman (the plaintiff) stated, or about one-half inch as estimated by another member of her family. It would seem that, in order for the opinions of the experts to be of any assistance to the jury, the condition in which the splints were applied to the arm should have been described. This point was not specifically called to the attention of the trial court. The plaintiff was content to call them 'side splints,' and one of the doctors inquired if the anterior and posterior splints were omitted, and was informed by counsel for plaintiff that they were. If the splints practically encircled the wrist, we fail to see that it would be very material whether they were termed side splints or anterior and posterior splints. While the place where Dr. Knott practised and treated plaintiff was mentioned, the practice about which the experts were interrogated was in no way confined to the practice in similar localities. 21 R. C. L. p. 385, § 30. The testimony in regard to the application of the splints was practically the only testimony indicating negligence on the part of the defendant, and the testimony of the experts was very material. We think it precluded the granting of the motion for a nonsuit, or the request for a directed verdict. It is unnecessary to speculate what the testimony would have been if all of the material elements had been called to the attention of the experts." It was also held that it is not a ground for striking out the testimony of a medical witness that it showed no qualification to answer the hypothetical question as to the treatment of a broken wrist, because the witness had never treated a fracture of this nature with infection. It appeared the witness was skilled in medicine and surgery, and the fact that he had never treated a case exactly like the one in question would not disqualify him from giving his opinion. As the plaintiff did not allege that the defendant did not possess the requisite knowledge and skill to treat the plaintiff, but that he failed to exercise such skill and knowledge, it was held error to refer, in an instruction to the jury, to possible lack of knowledge of the defendant, which reference might lead the jury to consider the defendant's qualifications. Judgment for the plaintiff was reversed.—Lehman v. Knott, Oregon Supreme Court, 196 Pac. 476.

Hypothetical Questions Including Matter Not in Evidence Excluded.—In an action by a physician for medical services to the defendant's wife, the defendant counterclaiming for damages for the plaintiff's negligence in treating the wife after childbirth, the Wisconsin Supreme Court holds that it was error prejudicial to the plaintiff physician to allow hypothetical questions to medical witnesses by the defendant's counsel as to the existence of pus in the uterus of the defendant's wife, in the absence of evidence as to the nature of the pus.—Schentzky v. Zants (Wis.), 182 N. W. 751.

Cross-Examination of Medical Witness Called Merely to Identify X-Ray Plates as to Treatment of Fractured Joint Excluded.—A physician, called merely for the purpose of identifying *x*-ray plates made by him showing a fracture of both bones of one of the plaintiff's legs, testified that he did not know whether the fracture had been reduced before the plates were made, and that he could not say whether or not it was a compound fracture. The Kansas Supreme Court holds that an objection to a question on cross-examination calling for his opinion whether or not a compound fracture could be reduced the same as any other kind was properly sustained, this not being proper cross-examination, because, although the witness was a physician, he was called merely for the purpose of identifying the plates made by him.—Simpson v. Schiff (Kan.), 197 Pac. 857.

Sufficient Indictment Charging Practising Without License Under West Virginia Statutes.—An indictment which avers that the defendant without first having complied with sections 9, 10, and 11 of chapter 150 of the West Virginia Code (secs. 5343-5345), governing applicants and the issuing of certificates of license to practise medicine and surgery in the State, and without first having obtained a State license so to do, as required by the laws of the State, did unlawfully practise medicine and surgery as defined in chapter 150, § 8aXII (sec. 5342l), Supplement 1918 of the Code, sufficiently charges the offense prescribed by the statute, and sufficiently negatives the fact of the defendant's being of the first class of practitioners described in said section 9. While practitioners of medicine and surgery since the amendment of said section 9 by chapter 22 of the Acts of 1889 have not been required to submit themselves to examination and obtain new certificates of license, nevertheless prior to that amendment and since the amendment and reenactment of said chapter 150 in 1882 (Acts 1992, c. 3), they have been required to have such certificates of license as a condition of the right to practise medicine and surgery, and the averments of the indictment were held sufficiently to negative the fact that the defendant was of the first class of practitioners described in the statute.—State v. Kirkpatrick, West Virginia Supreme Court of Appeals, 106 S. E. 887.

Hospital Held Public Charity, Not Liable for Negligence of Its Servants.—The Massachusetts Supreme Judicial Court holds that the Massachusetts Homeopathic Hospital, created by St. 1855, c. 411, and authorized to hold property for the support and maintenance of a hospital for sick persons, the recipient of a donation under St. 1890, c. 358, in consideration of maintaining not less than twenty free beds, and authorized by St. 1898, c. 137, to accept the property and funds of the Homeopathic Medical Dispensary held for charitable purposes, is a public charity, and therefore not liable to a patient for the negligent acts of its servants or agents.—Kidd v. Massachusetts Homeopathic Hospital (Mass.), 130 N. E. 55.

New York, October 22, 1921.

THE NEGATIVITY OF A NEGATIVE WASSERMANN.

THE old-time practitioner is fond of remarking that these young shavers nowadays can't make a diagnosis unless they have a laboratory along with them. This, we hope, is rather a heightened statement, but it is built upon the undoubted fact that far too much reliance is placed upon laboratory tests and too little upon the patient himself. This attitude tends naturally to neglect of physical diagnosis and the acceptance of the dicta of the laboratory as final. One wonders what would happen should the labels on specimens get mixed up occasionally. Probably the minister would be put on arsphenamine therapy and the typhoid fever patient served with steak and potatoes.

In a recent article, Dr. Ferencz Veress, professor of venereology at the University of Chuj, Roumania, calls attention to the unfortunate results which may accrue from attaching too much importance to a negative Wassermann reaction. As the professor justly points out, this reaction may be negative at any stage and with any severity of syphilis. Rather should clinical symptoms be searched for and properly evaluated, especially when the question is whether or not to discontinue antiluetic treatment. It may quite possibly be necessary to give a prolonged course of treatment even after the Wassermann reaction becomes negative. It is not difficult, of course, for a medical practitioner to realize the truth of this, and indeed most physicians who have occasion to treat many syphilitics soon come to hold the same idea themselves. What is not always appreciated, however, is the undue importance which the patient himself attaches to a negative Wassermann. Wishing to believe that he does not have syphilis or that he is cured, the patient is too likely to ignore the request of the physician that he have further examinations made, and go on his way rejoicing. Far better, should there be any clinical manifestations of the disease, it is to tell the patient, not that the test was "negative," but that it was not final and that probably several more will have to be done. This course of procedure is ordinarily entirely feasible when the usual relations exist between physician and patient and is quite justified for the latter's sake when there are any clinical evidences of lues. It is, of course, unwarranted when there is no logical reason to suspect the disease, but when the patient himself is suffering from syphilophobia. In such a case the practitioner should dwell with emphasis on the negative reaction.

Unfortunately many of the laity, knowing that they have contracted syphilis in the past or fearing they have done so, go directly to a laboratory and have a Wassermann reaction done. If this is negative, they are once conclude that they do not have syphilis and do not bother to see a practitioner or to take treatment. In this way necessary treatment may be neglected and the disease itself communicated to others owing to the patient's misplaced confidence in the one laboratory test. When the doctor thinks then of a negative Wassermann reaction let him think of it as indeed "negative." By itself it means exactly nothing. If a knowledge of this fact will turn his attention more to clinical symptoms the patient—and incidentally the physician—will be greatly benefited.

ASTHMA IN NURSLINGS AND CHILDREN.

ASTHMA in nurslings is generally overlooked or mistaken for bronchopneumonia or recurring bronchitis. In very young infants the affection does not assume the same clinical aspects as in adults; in the latter the paroxysms develop suddenly without premonitory catarrh of the throat or bronchi, while in infants and children up to the age of six years it is always accompanied or preceded by signs of tracheitis or bronchitis. The paroxysms of asthma generally appear in infants who are predisposed to colds, hoarseness, sneezing, or bronchitis. During an attack of rhinitis the infant is seized suddenly either at night or during the day with dyspnea, respiration increases—in adults it is usually slow—the nasal alæ are animated with movements, while a pulmonary whistling sound, especially during expiration, which is very prolonged, can be heard some distance from the patient. This noise is frequently interrupted by a paroxysmal cough and the patient is distressed, cyanosed, and pale. Auscultation reveals sibilant râles, especially during expiration, the respiration sound is short and obscure, percussion is normal with a slight tympanic sound. Occasionally some mucous râles can be heard, particularly over the pulmonary bases, which might lead one to suspect a bronchopneumonia, all the more so because the temperature is raised.

In infants the attacks last from one to two days with intervals of respite and exacerbation, the latter being more frequent at night. The attack usually ends suddenly. The asthmatic process may be mild or, on the other hand, assume the aspect of a suffocative catarrh. The

prognosis of the affection is good, and the younger the infant the greater are the chances of a permanent cure. When the first paroxysm of asthma occurs after the age of fifteen years the affection will last during the life of the patient, while if the onset occurs under the age of five years complete recovery will usually be noted by the age of ten, and is greatly favored by the exhibition of potassium iodide.

As is known, asthma is a spasm of Reisseissen's muscles with vasomotor and secretory disturbances that have been regarded as the result of an abnormal stimulus of the pneumogastric. It is admitted that the paroxysm is always provoked by some variable occasional cause, but always the same for each patient. In order that this cause shall act, the predisposed subject must offer a special constitution, the nature of which is not clear. Some stimuli, the inhalation of dust, the perception of certain odors or certain foods determine paroxysms of asthma by acting on the terminal filaments of the pneumogastric or on the bulbar origins of this nerve; therefore, the process has been thought to be due to a neurosis of the vagus or bulb.

This theory at present seems to be giving way to the opinion which regards asthma as the result of an anaphylactic shock. To maintain this hypothesis clinical and experimental observations have been taken as a basis. In the same subject it is usually the same cause which produces the paroxysm, so that the patient is in a way sensibilized. In the guinea pig anaphylactic shock is manifested by a spasmodic dilatation of the thorax similar to that occurring in asthma, and autopsy reveals a spasm of the bronchial muscles. The conditions of this sensibilization or predisposition to asthma are to be found in the arthritic heredity of asthmatic subjects, their parents having been subject to migraine, periodical vomiting, asthma, eczema, hemorrhoids, gout, diabetes, obesity, and other diatheses. And, in point of fact, in children one frequently observes the coincidence or succession in the same patient of eczema and asthma. Hutinel has seen attacks of asthma alternate with urticaria, prurigo, strophulus, or even periodical vomiting.

Landouzy formulated the theory of tuberculous asthma. The bacillary toxins sensibilize the organism and give rise to the paroxysm, the preexisting pulmonary lesion localizing the shock to the respiratory apparatus. As a proof Landouzy showed that the syndrome of asthma usually accompanied the manifestations of tuberculosis in the immense majority of cases. But Marfan points out that the cases observed by Landouzy were all in adults. Now, after the age of twenty years, nearly every individual in all civilized countries will have tubercle bacilli somewhere in the organism, and we know that of one hundred adults taken at random 97 per cent. will react to tuberculin. Therefore, in order to solve the problem very young asthmatics must be examined or those still free from tuberculous infection. Now, of the asthmatics less than two years of age the cutireaction essayed by Marfan several times in succession was always negative, excepting in a single instance of an infant nine months old. Therefore, asthma, in at least some subjects, is quite independent of any tuberculous infection.

PSYCHOTHERAPY IN PHTHISIS.

A POPULAR lay idea of the tuberculous patient is an emaciated individual with a hectic flush on his cheek, an unnaturally bright eye and an incurable optimism. This latter point has even been embodied in an aphorism to the effect that: "Patients having diseases below the diaphragm are depressed; above, exalted." An even more appealing idea, although not perhaps so widely held, is that the toxins of tuberculosis often stimulate the fires of genius and the indulgers in this romantic fantasy quote glibly the names of Stevenson, Chopin, *et al.*

Now all these theories have their origin in a fact which was dimly recognized many years ago and which is coming more and more into its own; that is, that certain peculiarities of individual psychology lead to habits of life and manners of thinking which inevitably predispose to certain very definite physical disorders. For example, the dementia precox patient, with his disinclination to exercise, his tendency to close, secluded places, his comparative physical immobility and often his uncleanness, easily becomes tuberculous. So we see in hospitals for mental disorder a large incidence of tuberculosis among precox cases and, conversely, reviews of the previous history of this class of patients, even in general hospitals, disclose many of them to be of the introverted type of make-up.

No one would pretend, of course, to treat phthisis by purely psychotherapeutic measures. At the same time, there is no doubt but what these would form an effective part of the therapy, if tried more generally. In that millenium to which psychiatrists look forward, where insanity will be treated by prevention instead of segregation, the child showing tendencies toward introversion will be directed toward healthier mental attitudes, and precox or tuberculosis or both will be prevented. Even where the disease is actually established, there is a vast and greatly neglected field for psychotherapy. These patients often, as is not surprising, develop pathological mental reactions which impede a cure and may indeed hasten the progress of the disease. These reactions may amount to true psychoses, such as confusional or paranoid reactions, or they may be such psychoneurotic reactions as fear or anxiety states. Often with the realization of the disease, the patient rapidly regresses to a rather infantile level where he is content to be waited upon and to let the disease take its course.

Such states are naturally rather intractable,

but much may be done in the way of prevention; and even when they are fully established intelligent psychotherapy may enable the patient to withdraw his interest from himself to some extent and assist in his own treatment. Of more use is psychotherapy when there exists such a condition as a morbid fear of hemoptysis or where the patient is unable, through some psychical reason, to tolerate certain articles of diet almost indispensable to recovery.

In short, the tuberculous patient will be found very frequently to suffer from wrong mental habits which tend materially to hinder his treatment. From this viewpoint each of these patients is a highly individual problem. Close study of his psychology, followed by the intelligent application of psychotherapeutic methods, will give the routine forms of treatment their utmost opportunity.

Unique Lesions of the Mucosæ (Koplik's Spots?) Due to Vaccination.

An efflorescence on the buccal mucosa suggestive of Koplik's spots would naturally lead in foundling and children's hospitals to isolation on the presumption that measles was imminent. This would invariably happen if measles already existed in the vicinity. The fact that the affected children had recently been vaccinated against smallpox would not alter the *status quo*. A careful study of the unusual behavior of vaccinia has failed to show that such a buccal efflorescence has ever occurred during this condition, whether artificially or naturally acquired. Yet Preisich, a pediatrist of Vienna, writing in the *Wiener klinische Wochenschrift* for August 18, 1921, xxxiv, 33, claims to have had this experience. The condition of redness, roughness, and loosening in some of the area of the buccal mucosa—the portions of the cheeks surrounding the orifices of Steno's duct—was associated in one child with a suspicion of conjunctivitis. The affected infants were all in the febrile period of vaccina. Further investigation showed in some subjects similar lesions of the border of the soft palate at the sides of the base of the uvula. But no measles-efflorescence developed in the skin, and the buccal lesions subsided with the vaccina fever. The closest resemblance exists between these lesions and the terminal appearance in Koplik's spots.

"Barbed Wire Disease" in Tuberculosis Sanatoria.

The so-called "barbed wire" or "wire fence" disease of war prisoners was described among others by Vischer of Zürich in 1918, and this author may have been the first to call attention to the fact that the same picture appears in sanatorium patients. Kollarits, a Hungarian physician, who has been sojourning in Davos, Switzerland, contributes an article on the latter phase of the subject in the *Schweizerische medizinische Wochenschrift* for August 11, 1921, li, 32. The symptoms may be readily summed up. The central point is the desire to get out of the institution. This is expressed by depression, insomnia, anorexia, dislike and distrust of the other inmates, personnel, and medical men, which lead to petty squabbles and animosities. This mental state is interwoven with the hopes and despair incidental to the progress of the case. The disease picture often comes on explosively. The patient of a sudden feels that he can no longer tolerate being under supervision. If possible he may at once leave the sanatorium for a hotel. Once in the latter there is a further reaction. The patient is now extremely lonely and on one occasion a rise of temperature of but 2-10 of a degree led the sufferer to wire his mother to come to Davos, a journey of 1000 kilometers. He next returned to the sanatorium as the lesser evil, but at once there returned the impulse to get away. He then left Davos altogether for Meran, entered a hotel and then at once repaired to a local sanatorium. In two weeks' time he was in Davos again, constantly impelled by the "barbed wire" sensation, yet having always the counter impulse to get "within the fence" again. Treatment is of the simplest—merely tell the patient he is free to leave the institution at any time and the motive for barbed wire disease no longer exists. This course could not of course be pursued with war prisoners.

News of the Week.

Baltic States Set Up First Wall Against Cholera.—According to a report from the American Red Cross Commission to Europe, the famine stricken districts of Russia from which the emigration started are so affected with cholera that combative measures are impossible under present circumstances. The cholera epidemic is gradually spreading over the country, and the rest of Europe is faced with the danger of cholera. Three Baltic States, Latavia, Esthonia and Lithuania, have assumed the responsibility of making a sanitary cordon against the spread of the disease. A Baltic conference was suggested by Lieutenant-Colonel Edward W. Ryan, Red Cross Commissioner to Western Russia, and this conference was held in Riga under his honorary presidency, with the assistant director of the Latavian Health Department, Dr. Livitzki, in the chair. The conference agreed to adhere to the Paris convention of 1903-1911, and it was decided to consider the decrees of the convention of Paris as binding for the three Baltic States, and to induce the representative Foreign Offices to take the necessary steps for their formal adherence to the convention. It was decided by the conference to request the aid of the American Red Cross in organizing the work, so that the first wall against cholera should not be in danger of collapse, and the infection spread from the harbors and the borders of the Baltic States throughout the world.

The conference also dealt with the internal measures to be taken against cholera, and unanimous agreement was reached on this subject. A restriction of railway traffic was found to be necessary in order that the health departments might confine the right of railway travel to such persons only as could show a certificate of health issued by the local authorities. Compulsory vaccination against cholera was not provided for as an invariable rule, but the medical officer in charge was authorized to apply compulsion should circumstances call for such action.

County Commissioners Favor Tuberculosis Hospitals.—The County Commissioners of Pennsylvania, in their annual convention held in Harrisburg, September 29, 30 and October 1, passed resolutions recording their approval of the plan providing hospital care for the persons in each county afflicted with tuberculosis. The convention at the same time voted to name a committee of five commissioners to consider the question of hospital care for the tuberculous and those afflicted with other contagious diseases. Seven counties in the State will hold referendums next month on the question of maintaining tuberculosis hospitals.

Anthrax in New York.—The death of Michael F. Farley, formerly representative from the Fourteenth Congressional District of New York, from anthrax believed to be caused by a shaving brush, has revealed the fact that the Health Department has been carrying on a campaign for several months to prevent the spread of anthrax germs through the importation of foreign hair and hides. The Division of Industrial Hygiene has barred the entry of 10,000 shaving brushes from Japan, and has compelled the return of the shipments on the ground of anthrax infection. Similar action has been taken with regard to large shipments of hair from Russia and Siberia. Fifty-seven bales of hides from China have been excluded because they were found to be infected with anthrax. In the last nineteen months there were thirty-four cases of anthrax here, twenty of which were shaving brush infections. There was a total of eleven deaths in this group, nine of them shaving brush victims. One of the other two deaths was caused by an anthrax tooth brush. The other resulted from an infected scrubbing brush.

Physical Examinations for New York's Vagrants.—Steps have been taken in a program to examine physically every man of the 40,000 or more now classed as "vagrants" in New York. On the theory that a large percentage of the men in the parks and without homes here are diseased, the Department of Public Welfare is making arrangements with the city's hospitals for commitment of many men. All the men found loafing in the streets and parks will be placed under temporary arrest, it is understood, by the police. The roundup will start as soon as cooperation can be had between the Welfare, Health and Police Departments, according to Commissioner Bird S. Coler, head of the former. The men "arrested" will be taken to the Department of Health, and those needing hospital care will be held prisoners until cured.

Birth Control Clinics.—Plans for the First American Birth Control Conference, which will be held in the Hotel Plaza, November 11-13, 1921, are under way. It has been announced that following the conference clinics will be opened in several of the Southern States where there are no laws prohibiting them, and that, according to present arrangements, more than ten of these clinics will be in operation within the next year. Among those on the Conference Committee are Professor Walter B. Pitkin, Dr. S. Adolphus Knopf, Dr. Mary I. Bigelow, Dr. and Mrs. Frederick Peterson, Dr. Donald R. Hooker, and Miss Lilian Wald.

Hospital Notes.—Architects are preparing plans for an addition to the Wilkes-Barre (Pa.) Hospital. The estimated cost of the new structure if $125,000.

Arrangements have been made for the erection of a new hospital in Phillipsburg, Pa.

Work has been begun on the addition to the Syracuse (N. Y.) Hospital. The plans for the new building call for the expenditure of $40,000, and provide for a modern maternity service.

Ground was broken on October 9 for the new Beth Israel Hospital in Livingston Place, between Sixteenth and Seventeenth Streets, New York. The estimated cost of the new building is $3,000,000. It will be thirteen stories high and furnish accommodations for 500 patients. The site for the new building was purchased four years ago for $400,000. The hospital has $1,125,000 with which to start building operations and expects to raise the remainder before the completion of the building.

New York Hospital Anniversary.—The Society of the New York Hospital, which controls the New York and Bloomingdale hospitals and the Campbell Cottages for Convalescent Children at White Plains, and which was chartered by King George III, will celebrate its 150th anniversary on October 26. Ceremonies will be held in Trinity Church, when Bishop William T. Manning, Governor Miller, Elihu Root, and others will speak.

Dr. H. H. Rusby, head of the Mulford biological exploration party, has sent a report to the Columbia University School of Pharmacy announcing that new drug plants and species of insects have been discovered in the Amazon River basin. The expedition is proceeding down the Bopi River in the prosecution of its researches and has penetrated into the little known regions of the interior of Bolivia.

Intensive Course in Tuberculosis.—An Institute for Physicians will be held by the Boston Tuberculosis Association on October 26 and 27 in the amphitheatre of the Massachusetts General Hospital. It is to consist of an intensive course of lectures on tuberculosis. The institute has been organized by a committee of the Association, consisting of Dr. Cleaveland Floyd, chairman; Dr. Edward O. Otis, Dr. William C. Woodward, Dr. John B. Hawes, 2d, and Dr. Randall Clifford. The lectures will be delivered by authorities on tuberculosis from various parts of the country.

Memorial to Dr. E. L. Mooney.—Members of the Lieutenant Edward Mooney Post, Veterans of Foreign Wars, Syracuse, N. Y., at a meeting on October 6, adopted resolutions to erect a memorial tablet to the late Dr. Edward L. Mooney, father of the boy after whom the post is named. A committee has been appointed to draft a plan for a tablet to be placed in the rooms of the post.

Dinner to Professor Dessauer.—Dr. Charles H. Jaeger of New York gave a dinner on the evening of October 14 at the Hotel Plaza for Professor Fredor Dessauer of the University of Frankfort, who came to this country on the invitation of the American Roentgen Ray Society to read a paper at the annual congress held in Washington recently. The guests included the physicians and surgeons of the Lexo Hill Hospital.

Dr. Oliver S. Hillman has removed his office to 114 East Fifty-fourth Street, New York City, where he has opened a pathological laboratory.

Dr. Rene Ledoux Lebard of Paris, France, addressed the Section on Historical Medicine of the New York Academy of Medicine at its meeting held

October 13. His subject was, "Color Print Illustration of Medical Books up to the Year 1800."

Dr. John M. Quirk of Watkins was elected president of the Sixth District Branch of the Medical Society of the State of New York at its annual meeting held in Watkins, October 4, 1921.

Gifts and Bequests.—Harvard University is the recipient of a bequest of $200,000, the income of which is to be devoted to the investigation of the origin and cure of cancer, under the will of Hiram F. Mills of Hingham, Mass.

A gift of $100,000 by T. F. and H. E. Manville toward the fund of $750,000 needed for the completion of the Fifth Avenue Hospital, New York, has been announced.

The will of Mrs. Jemina S. Sims bequeaths $10,000 each to the Manhattan Eye and Ear Hospital, the New York Eye and Ear Hospital, New York City, and the Masonic Hospital, Ithaca, N. Y.

By the will of the late Edith E. Collins of Lower Merion the sum of $10,000 is bequeathed to the Hospital of the University of Pennsylvania for the maintenance of beds in the orthopedic ward in memory of the testator's parents, S. Conard and K. E. Conard.

The will of the late Robert Foland of Philadelphia bequeaths $2,000 to the Children's Hospital and $1,000 to the Chestnut Hill Hospital.

Free Health Lectures.—The Public Health Education Committee of the Medical Society of the County of New York in cooperation with the New York Academy of Medicine announces a course of free public lectures on health education and prevention of diseases, to be given at the New York Academy of Medicine, 17 West 43d Street, from October 14 to December 14, 1921. The first of these lectures was delivered on October 14 by Dr. Ralph Lobenstine, who spoke on "The Proper Care of the Expectant Mother." Following him Dr. George W. Kosmak spoke on "The Necessity for Proper Care for the Mother after the Delivery of Her Child." On October 19, talks on the "Care of the Pre-school Child" were given by Miss Mary Arnold and Dr. Louis Schroeder. On Friday, October 28, at 8:15 P. M., the subject will be "Mental Hygiene in the Community," and the speakers will be Dr. A. J. Rosanoff and Dr. Mary MacLaughlin. On Wednesday, November 2, at 4 P. M., the subject will be, "What the Public Should Know about Cancer." At this time Dr. Charles E. Farr and Dr. Elise S. L'Esperance will speak.

The New York and New England Association of Railway Surgeons will hold its thirty-first annual meeting at the Hotel McAlpin, New York, October 29, 1921, under the presidency of Dr. J. F. Black of White Plains, N. Y. On Friday, October 28, clinics will be held at the Hospital for the Ruptured and Crippled in the morning and at the Post-Graduate Hospital in the afternoon.

Medical Society Elections.—The Indiana State Medical Association, at its annual meeting held in Indianapolis, September 28-30, elected the following officers for the ensuing year: *President*, Dr. W. R. Davidson, Evansville; *First Vice-President*, Dr. Thomas Jones, Anderson; *Second Vice-President*, Dr. William Ashbury, Terre Haute; *Third Vice-President*, Dr. E. S. Jones, Cameron; *Secretary-Treasurer*, Dr. Charles N. Combs, Terre Haute.

The Valley Medical Association, at its semi-annual meeting held in Winchester, Va., October 1, elected the following officers for the ensuing year: *President*, Dr. Charles C. Conrad, Harrisonburg; *First Vice-President*, Dr. Hunter H. McGuire, Winchester; *Second Vice-President*, Dr. Harry Wallace, Greenville; *Secretary*, Dr. Alexander F. Robertson, Jr., Staunton; *Treasurer*, Dr. J. Y. Beidler, Harrisonburg.

The Medical Society of Pennsylvania, at its seventy-first annual convention held in Philadelphia, Oct. 6-8, 1921, elected the following officers for the ensuing year: *President*, Dr. Lawrence Litchfield, Pittsburgh; *Vice-Presidents*, Dr. John B. Carnett, Philadelphia; Dr. Victor Chanel, Williamsport; Dr. John B. Murray, Washington, Pa., and Dr. Spence M. Free, Du Bois; *Secretary*, Dr. Walter F. Donaldson, Pittsburgh; *Assistant Secretary*, Dr. C. B. Longenecker, Philadelphia; *Treasurer*, Dr. J. B. Lowman, Johnstown.

Obituary Notes.—Dr. James Raynor Hayden of New York was found dead on the golf links of the Rockaway Hunt Club at Cedarhurst, L. I., shot through the head, on October 10. He was fifty-nine years of age. Dr. Hayden was graduated from the College of Physicians and Surgeons, New York, in 1884, and was formerly a professor in that institution. He was a member of the American Medical Association, a Fellow of the American College of Surgeons, a member of the American Urological Society, of the American Genito-Urinary Association, the International Société d'Urologie, the New York Academy of Medicine, and many other medical and lay organizations. He was formerly on the staff of Bellevue and Roosevelt Hospitals, and was consulting genitourinary surgeon to St. Joseph's Hospital, Yonkers, N. Y.

Dr. Everind A. Kirkpatrick, a graduate of McGill University Faculty of Medicine in 1888, died at his home in Halifax, Nova Scotia, on September 23, at the age of sixty years.

Dr. Robert A. Toms of Noroton, Conn., a graduate of the New York Eclectic Medical College in 1896, died on October 4, at the age of fifty-two years. Dr. Toms formerly practised medicine at Kenmore, N. Y.

Dr. William S. A. Castles of Memphis, Tenn., a graduate of Vanderbilt University Medical Department, Nashville, in 1882, died in a local hospital on September 29, at the age of sixty-two years.

Dr. John S. Frazer, a graduate of the Michigan College of Medicine in 1885, died of heart disease at his home in Detroit, Mich., on September 29, at the age of sixty-four years.

Dr. Asa A. Allen, a graduate of the New York Homeopathic Medical College in 1876, died suddenly at his home in Edgewood, R. I., on September 25.

Dr. O. C. Walker of Alliance, Ohio, a graduate of the Cleveland College of Medicine and Surgery in 1913, was assassinated at his home on September 27. He was thirty-five years of age.

Dr. Milton Howard Fussell of Philadelphia died on October 15 on a train on the way from Lock Haven to his home, at the age of sixty-six years. He was graduated from the medical department of the University of Pennsylvania in the class of 1884. He was for a number of years assistant in medi-

cine, later assistant professor of medicine and since 1911 profesor of applied therapeutics in the university. He was a member of the Philadelphia County Medical Society, the Medical Society of the State of Pennsylvania, the American Medical Association, the Pathological Society of Philadelphia, the Philadelphia Pediatric Society, the Philadelphia Neurological Society, and the Association of American Physicians, and a Fellow of the College of Physicians of Philadelphia. He served during the recent war with the rank of captain as a member of a Tuberculosis and Cardiovascular Board at Fort Niagara and Gettysburg, and also as a member of a Medical Advisory Board. He was author of "Differential Diagnosis of Internal Diseases" and editor in charge of the revision of "Tyson's Practice of Medicine."

Dr. EDWARD G. JONES of Atlanta, Ga., a graduate of the Atlanta College of Physicians and Surgeons in 1900, and a Fellow of the American College of Surgeons, died on October 6, at the age of forty-eight years. He was formerly president of the Georgia State Medical Association, and professor of surgery at Emory University.

Dr. JOHN H. MURPHY, a graduate of Harvard University in 1893, died at his home in Dorchester, Mass., on October 6, at the age of forty-eight years.

Dr. A. CLARENCE MUSGRAVE of Toledo, Ohio, a graduate of the Eclectic Medical School, Cincinnati, and also a graduate in dentistry, died in a local hospital following an abdominal operation, on October 4, at the age of forty-seven years. During the recent war he served nine months as first lieutenant in the dental corps, overseas.

Dr. THOMAS CLAYTON FRAME, a retired physician of Dover, Del., died on October 3, at the age of eighty-one years. He was graduated from the University of Pennsylvania School of Medicine in 1866. He later graduated from the Law School of the University of Pennsylvania and from the University of Edinburgh, Scotland, in medicine.

Dr. WALTER LYTLE PYLE, a graduate of the University of Pennsylvania School of Medicine in 1893, died at his home in Merion, Pa., on October 8, at the age of forty-nine years. He was a member of the American Medical Association, the American Ophthalmological Society, the Philadelphia County Medical Society, and the Medical Society of the State of Pennsylvania. He was for a time chief resident physician at the Emergency Hospital, Washington, D. C., and was later ophthalmologist to the Polyclinic and Wills Eye Hospitals, Philadelphia; author of a "Manual of Personal Hygiene" and editor of a "System of Personal Hygiene" and with Dr. George M. Gould, co-editor of "Anomalies and Curiosities of Medicine and Surgery."

Dr. EVERETT SHIPLEY of Seaford, Del., a graduate of the College of Physicians and Surgeons, Baltimore, in 1891, died suddenly of angina pectoris on September 30, at the age of sixty-six years.

Dr. ALBERT W. CARSON, a graduate of the Medical College of Ohio, Cincinnati, in 1875, died at his home in Richland, Kan., on September 29, at the age of seventy-one years.

Dr. JOHN W. ELLIOTT of Linden, Ind., a graduate of the University of Louisville Medical and Surgical Department in 1897, died on October 1, at the age of fifty-nine years.

Correspondence.

HOW TO INCREASE THE DEATH RATE FROM CANCER.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—*Health News* is an official publication of the New York State Department of Health, Division of Public Health Education. The August, 1921, issue of this publication contains an article upon cancer by Francis Carter Wood, M.D., director of the Institute of Cancer Research, Columbia University, New York City. This article is, perhaps, the most remarkable article upon cancer that I have ever read. I quote a few sample passages. To be thoroughly appreciated, the article should be read as a whole. (*All italics are mine.*)

"This [yearly] *increase in the number of deaths from cancer* . . . is partly, at least, due to improvements in methods of diagnosing the disease." (Paragraph 1.) Then: "It is, therefore, the duty of every practitioner to remove for microscopic examination specimens of tumors which can not be diagnosed in any other way, *for it is only by such means that the mortality from cancer can be reduced.*" (Closing sentence.)

"Others, again, will grasp at the *false hope* offered by the magic reputation of radium and *x*-ray, and *most of those who do so will be added to the death list.*" (Paragraph 7, explaining why there are so many deaths from cancer.) Then: "*Every tumor* which has passed beyond the stage where satisfactory operation is possible *should be treated with x-ray or radium*, and *all patients operated upon should receive a post-operative course of x-rays to delay or prevent any possible return of the tumor* from particles which have escaped the knife."

I like the "false hope" paragraph, followed in the next paragraph by advice to use said false hope at some stage in every last case of cancer. And fancy "every practitioner" cutting out samples of "tumors which cannot be diagnosed in any other way"—it's their "duty"!

This is an educational document! For the public! With the official sanction of the New York State Department of Health! At public expense the public is being taught what isn't so about cancer in order to avoid death from cancer; and physicians are informed that it is their "duty" to do an impossibility! It would be a roaring farce if it were not tragic.

SEELYE W. LITTLE, M.D.

ROCHESTER, N. Y.

RELATION OF THE ADRENAL CORTEX TO GRAVES' DISEASE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—This is to call your attention to an editorial article, "Possible New Light on the Nature of Exophthalmic Goiter," which appeared October 8, 1921, in the *Journal of the American Medical Association*. The writer of the editorial comments on the experimental work of David Marine and E. J. Baumann which was published in the *American Journal of Physiology*, August, 1921, under the title, "Effect of Suprarenal Insufficiency (by Removal or Freezing) in Rabbits." The chief interesting point in their admirable work is the fact that in supra-

renalectomized rabbits the basal metabolism is increased in a similar manner as in exophthalmic goiter, and for this phenomenon the cortex and not the medulla is responsible. Inasmuch as until now a primary thyroid hyperfunction was considered as the sole cause for increased metabolism in Graves' disease their work is bound to revolutionize our modern conceptions. The writer of the editorial also comments on the fact that articles had appeared in the journal in which views were expressed on purely hypothetical grounds in the same direction.

In a paper: "The Possible Relation of the Adrenal Cortex to Graves' Disease," etc., read before the Harlem Medical Association, November 4, 1920, and published in the MEDICAL RECORD, February 19, 1921, which was discussed by Dr. Emil Goetsch, Dr. George Draper and Dr. Samuel Bandler, an explanation in full was given of the relation of the adrenal cortex in Graves' disease. If one compares this article with the experimental work of Marine and Baumann it will become evident that there is no difference. In summing up the paper, I wrote: "Some of the clinical symptoms found in individuals afflicted with Addison's disease, such as emaciation, asthenia, and hyperpigmentation, manifest themselves, truly to a lesser degree, in individuals suffering from Graves' disease. The symptoms have been shown to be due chiefly to various degrees of cortical deficiency. Because of the mild grade of cortical hypofunction in hyperthyroid states the above mentioned symptoms are not as frequent or as pronounced as in Addison's syndrome. The hyperpigmentation in Addison's disease as well as in Graves' disease is due to the same cause, *i.e.* to the increased retention of uric acid in the blood on account of adrenal cortical insufficiency." A suggestion of treating patients suffering from Graves' disease with adrenal cortex was made.

My purpose in writing these lines is an attempt to correlate my clinical observations with the experimental work of Marine and Baumann to whom the credit belongs for establishing a definite link in the chain of the relation of the adrenal cortex to Graves' disease.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, September 30, 1921.

The National Insurance Act.—Somewhat of a bombshell has been dropped into the camp of the panel medical practitioners, those who practise under the National Insurance Act, by the announcement of Sir Alfred Mond, the new Minister of Health, that he proposed to reduce the capitation fee paid to panel doctors from eleven shillings to nine shillings and sixpence or thereabouts. The present total cost of medical benefit under the act is about £8,000,000, of which medical men receive about £6,700,000. The carrying into effect of the proposal of the Minister of Health would mean a reduction of the government share of the payments to the extent of about £2,000,000. It is believed by some that this is only a part of the truth, and that really the government intends to withdraw from participation in the Insurance Act altogether. Perhaps the attitude of the two leading medical journals of this country possesses some significance; the *British Medical Journal* has ranged itself almost unreservedly on the side of the panel practitioners, while the *Lancet* in its issue of September 24 published a leading article which seemed to hint that if certain things came to pass government financial support might be withdrawn entirely. However, the *Lancet* editorial rightly pointed out that the act had as yet not had a fair trial and went on to show that in spite of the war which paralyzed development, the act had worked so well for the friendly societies that they now had at disposal a surplus large enough to be coveted for a number of useful purposes. The medical practitioners themselves who were at first opposed to the scheme, now welcomed insurance practice, especially in industrial districts. Moreover, it must not be assumed that if the state refused to continue to contribute its quota toward health insurance, the contributory principle would fall to the ground. It appears more than likely that the friendly societies will still desire to offer medical benefit, making arrangements directly with the medical profession. The government must economize in view of the immensity of the unemployment problem, and as the Ministry of Health and its policy have been unpopular with the masess from the beginning economy will commence with the Ministry of Health. So far as the question of the proposed reduction of the capitation fee of the panel practitioners rests between the Ministry of Health and these practitioners, the official contention is that medical men have benefited enormously under the panel system. The panel practitioners, on the other hand, hold that they are not excessively paid and some of them even suggest that the broom of economy should be used to sweep out many if not most of the highly paid medical bureaucrats at the present time directly employed by the Ministry of Health. It is thought by certain of the would-be cognoscenti that the government contribution to the National Insurance Act will cease entirely in the near future and that if the medical men raise a great disturbance over the matter the death of the act will probably come quickly.

Post-Graduate Medical Study in Glasgow.—A central organization has been formed, the Glasgow Post-Graduate Medical Association, for the purpose of arranging, coordinating, and administering post-graduate medical education in Glasgow and the West of Scotland. General and special courses will be arranged and duly advertised. A comprehensive permanent scheme has been adopted and with its wealth of clinical material it is confidently anticipated that Glasgow will become one of the leading centers of post-graduate medical teaching.

Increase of Tuberculosis in Glasgow.—At a meeting of the subcommittee on the Prevention of Tuberculosis held in Glasgow on August 22 last, Dr. A. K. Chalmers, the Medical Officer of Health, reported an increase in the number of cases of pulmonary and other forms of tuberculosis. It was stated that there were now 11,634

cases under observation as compared with 10,895 for the same period last year—133 cases were awaiting admission to sanatoriums and 195 to hospitals; while 3,703 were attending dispensaries for treatment.

Population of Glasgow.—Details of the recent census have just been published. Glasgow's position as second city of Great Britain remains well established with a population of 1,034,069 inhabitants as against 1,005,487 ten years ago. The females predominate by 24,979.

Plastic Surgery of Facial and Jaw Deformities.—In previous London letters reference has been made to the remarkable results effected in plastic surgery of facial and jow deformities at Sidcup, near London, by Major H. D. Gillies and colleagues. A year or more ago Major Gillies visited America and gave lectures and lantern-slide demonstrations on his especial branch of surgery, and has published recently a book on the subject which was favorably commented on in one of these letters. Of course, the war brought plastic surgery of facial and jaw deformities greatly into prominence, and there were among American surgeons and dentists at the front some very distinguished pioneers and exponents of this comparatively new art. It must be borne in mind that the dentist has as much to do with the success of this kind of surgery as has the surgeon. Indeed, it seems obvious that without the dentist's technical and mechanical knowledge and skillful cooperation the surgeon would be at a loss, or, at any rate, unable to bring about the brilliant results which they have achieved working together. At a meeting of the Royal Medico-Chirurgical Society of Glasgow, held some little time ago, Major Gillies gave a lantern-slide demonstration of the facial and jaw reconstruction done at Sidcup, assisted by the chief dentist at Sidcup, Dr. Thomas Jackson, who made some instructive remarks on the matter. He pointed out that Major Gillies had described the principles of plastic surgery and their application to civil cases, and had referred frequently to the necessity for close cooperation between surgeon and dentist. In no other two branches of surgery so widely separated and so absolutely different was such a copartnership essential for the attainment of the ultimate result. Such cooperation was seldom seen in civil practice, but although his experience was confined to war injuries, he was convinced that it was essential to all types of plastic surgery and every day he saw this point more strongly emphasized. Men were being admitted at Sidcup now who, wounded in the early months of the war, were untreated or neglected in the great rushes which followed. Although it was possible to improve these cases, the long delay had rendered the patients unwilling to accept any extensive treatment recommended. However, the point of Dr. Jackson's remarks to which it is particularly desired to draw attention, is that the experience of the war has immensely improved plastic surgery of the face and jaw, and that the improvement should be taken advantage of in civil practice. Moreover, in order to gain the best results there must be close cooperation between the dentist and the surgeon.

2. Subluxation of the Shoulder—Downward. Frederic J. Cotton.
3. Mental Responsibility and Petty Crime. D. A. Thom.
4. The Surgical Treatment of Ulcer and Cancer of the Stomach. F. B. Lund.

1. Non-Tuberculous Pyelonephritis.—Arthur H. Crosbie asserts that most cases that are called pyelitis are really pyelonephritis. This is practically always true of the pyelitis of children and also of that of pregnancy. Almost any of the pus organisms may cause the disease. Examination of the urine always shows pus and the offending organisms. At some time during pyelonephritis, ureteral catherization should be done and the divided urine examined and cultured, and pyelograms made. It is preferable to wait for a few days before passing any instruments into the bladder. Cystoscopic examination during the acute stage may show a very marked cystitis. Frequently one sees the so-called beefsteak bladder. This generally clears up as the process in the kidney subsides. A great many of these so-called acute hematogenous kidneys are removed that would get well if left alone. If one kidney is removed it leaves an impaired kidney on the other side. In pyelonephritis complicating pregnancy the writer does not believe the pyelonephritis disappears until after the uterus is empty. Acute pyelonephritis should be treated expectantly. It is most important to force fluid; one should not be satisfied until the output exceeds one hundred ounces in twenty-four hours. In especially severe cases it is well to begin with hypodermoclysis. If the infection is by the colon bacillus the alkalis are of help. If an acute pyelitis becomes chronic there is generally some obstructive lesion to account for it. If no abnormality can be found, most cases of chronic pyelonephritis can be improved and some cured by pelvic lavage. For this the writer has been using a fairly strong solution of silver nitrate, but recently has been using mercurochrome 2½ per cent. with much better results. It is especially good when the condition is nothing more than a bacilluria. No case should be operated upon until one is sure of the necessity.

2. Subluxation of the Shoulder—Downward.—Frederic J. Cotton calls attention to a lesion which he finds common but apparently unwritten—the subluxation of the shoulder downward not from a single trauma, but from the weight of the arm made possible through gradual exhaustion of the muscles—primarily of the deltoid. He has observed this for years in case after case as a complication of shoulder and arm injuries. If neglected it become a troublesome complication. Many of the cases ordinarily listed as circumflex paralysis belong to this group. It seems that if we have an injured arm treated with traction by the weight of the arm or treated by any method that does less than carry the full weight of the arm, then, if the muscles are not strong, and if the arm is a heavy one, there is often a stretching paralysis of the deltoid and superspinatus muscles that lets the head of the humerus drop down. This is readily overlooked, but readily verified by finding a groove below the acromion to the outer side, often visible, always easily felt. Treatment consists of early massage, and, just as soon as the main damage makes it practicable exchange of traction for support, and effective support of the whole arm.

1. The Etiology and Treatment of Eclampsia.—Barton Cooke Hirst discusses various theories as to the etiology of eclampsia and expresses the belief that the origin of the toxins of eclampsia is mainly in the fetal body; to a less extent in the placenta. When these toxins are thrown into the maternal system overburdened organs break down, and this is more likely to occur if a heavy proteid diet, an inactive skin, and sluggish bowels increase the work they have to do. If one accepts this etiological theory there are four therapeutic principles to be considered, namely, elimination, the sedative treatment, measures to reduce blood pressure, and if the patient is not yet delivered, the operative treatment. Since in every case of eclampsia the patient has an acute parenchymatous nephritis and is uremic as well as toxic, the writer employs diaphoresis and catharsis, energetically sweating the patient in a sweat cabinet every four hours for thirty minutes and supplying the subtracted fluid by proctoclysis—a quart of water with an ounce of bicarbonate of sodium by the drop method midway between the sweats. He always begins by washing out the stomach and using the stomach pump to instil a purgative, using 2 ounces of castor oil with 2 drops of croton oil. If the patient is able to swallow this is followed by repeated doses of concentrated epsom salts solution every half hour until 2 ounces are taken. If there is much edema, 20 grains of compound jalap powder is administered. Anesthetics are not used. Morphine alone is depended upon, but is only administered if convulsions are violent and frequent. To reduce blood pressure, an initial dose of ten minims of veratrum viride and the subsequent administration of 1/100 of a grain of nitroglycerin every four hours is most efficacious. Venesection is done routinely to the extent of 16 ounces if the systolic blood pressure is above 180. Operative treatment by cesarean section is reserved for those cases in which the patient has not responded to the treatment above outlined, and in which there has been no progress in labor. During the last five years in the writer's service at the Maternity Hospital of the University of Pennsylvania there have been 89 cases of eclampsia, with a maternal mortality of 21.3 per cent., and an infant mortality of 36 per cent. If allowance were made for four patients who died within an hour of admission, the mortality rate would be 15 per cent.

4. Prophylaxis in Carcinoma of the Cervix.—Irving Smiley epitomizes his conclusions on this subject as follows: The morbidity and mortality of cervical cancer operations at the present writing is approximately 40 to 50 per cent. Chronic endocervicitis is an established precursor of cervical cancer. Tracheloplasty correctly executed is a cancer prophylactic, hence the teaching to postpone all tracheoplastic procedures until after the child-bearing period, still advocated by some, thus exposing the irritated cervix to further traumatism, is both fallacious and pernicious.

7. The Comparative Value of Whole Ovarian Extract, Corpus Luteum Extract, and Ovarian Residue in Menstrual Disorders.—John Cooke Hirst holds that of all the glandular extracts at present in use, none are more valuable or wider in their application than the various preparations of the ovary. As a result of his experience he states that results are not invariable with any extract, but if intelligently used, a good degree of success can be expected; excepting always the use of ovarian residue, where the results are considered decidedly nebulous. Results are often slow, particularly in menstrual disorders, and patience is one of the prime requisites, in both patient and doctor. Results are most prompt in the menopause with the whole ovarian extract, and in the nausea of pregnancy with corpus luteum extract. Co-operation between physician and patient is needed, and overoptimistic statements are to be avoided. The tendency is to expect too much and too quickly. The most discouraging results are with the cases of obesity and amenorrhea. It is probable that future developments will be along the lines of pluriglandular therapy, due to the probable correlation between the pituitary, thyroid, mammary gland, suprarenal, and ovary, rather than in the use of single extracts. Especially will this hold true in the developmental anomalies of the genitalia.

8. Dysmenorrhea.—John Van Doren Young outlines the lesions of true dysmenorrhea, a condition without gross pathology, and urges that the endometrium be spared, because it is a functioning organ and seldom involved as a causative factor of dysmenorrhea. He points out that pathological conditions of the myometrium are causative factors in the production of dysmenorrhea as is borne out by the relief obtained in some cases by the use of the stem pessary, and the usual relief after childbirth, as both undoubtedly develop the myometrium, dilatation of the cervix being only a secondary result. A warning is sounded, however, against the use of the stem pessary, even of glass, in the presence of infection. In searching for a method of producing rhythmical uterine stimulation, and at the same time hyperemia, with the idea of developing the myometrium and improving the pelvic circulation, Young has devised an instrument which is an application of the Bier's hyperemia method to the uterus. It consists of a suction syringe, a rubber tube with vent valve, and a long glass cup which fits over the cervix. Cups may be made of any size or shape to meet any indication. The value of this instrument is ease of application and rhythmical regulation of the stimulation. The exhaust pump is operated by the nurse for from five to ten minutes. The instrument is also useful for emptying infected cervical glands and removing viscid cervical mucus, in both cases rendering the application of iodine or other medication more effectual. In the treatment of dysmenorrhea, the instrument should be applied twice a week at first, then once a week, and later just before the menstrual period.

3. The Value of Drugs in Internal Medicine.—Lewellys F. Barker states that we are witnessing a cautious revival of the use of drugs in the treatment of disease following the reaction of the last half of the nineteenth century against the scandalous abuse of the "shotgun prescription." He surveys briefly the help offered to the physician in his daily work by modern pharmacotherapy under the headings etiological pharmacotherapy, functional pharmacotherapy, regulatory pharmacotherapy, and symptomatic pharmacotherapy, and expresses the opinion that the internist looks on the use of drugs in therapy more hopefully now, perhaps, than ever before. Adequately to make use of the pharmacotherapeutic means at his disposal, the internist must have mastery over a large body of facts. He must be well trained in normal and pathologic physiology, and should have become acquainted with the known facts of etiology and pathogenesis. He should have learned in the pharmacologic laboratory the effects of the more important drugs on the normal

animal body; and he should have had opportunity in the hospital wards, and in the laboratory of experimental pathology and therapy, to observe the changes that can be produced by drugs in disease. Very few have as yet had opportunity for the latter, but the medical schools should provide for it in the future. Our teaching hospitals at present are, perhaps, more diagnostic institutes than institutes of therapy. It might possibly be wise to divide our medical clinics into two parts, patients entering one division for general diagnostic study and emergency measures, to be transferred afterward to the other division for full treatment, the effects of which could be carefully observed by the students. The internist with such a training will be prepared to institute rational therapy when this is possible. He will know how to make a judicious use of empiric therapy when a rational foundation is lacking.

6. The Ocular Menace of Wood Alcohol Poisoning.—S. Lewis Ziegler has made an intensive study of wood alcohol through which he has reached the following conclusions: (1) Wood alcohol is the most deadly poison used in daily commerce. (2) One teaspoonful has been known to cause blindness and one ounce to cause death. (3) The port of entry may be through the mouth, nose, or skin. (4) Wood alcohol should be identified by Robinson's test. (5) It is a protoplasmic poison possessing a selective affinity for the delicate nerve tissues of the eye. (6) Its biochemistry is modified by oxidation, first to formaldehyde, and then to formic acid, both of which are corrosive poisons. (7) If formic acid is present in the urine, it will promptly reduce Fehling's solution, thus suggesting to the inexperienced a false diagnosis of diabetes. (9) Van Slyke's test will reveal acidosis in the early stages and alkalosis later. (10) Sudden blindness with vomiting and abdominal pain should always arouse suspicion of methyl alcohol poisoning, especially if diplopia or ptosis is associated. (11) Papillitis, sector-like atrophy, and sudden sclerosis of the nerve-head are equally typical fundus lesions. (12) Symptoms of pituitary injury are most suggestive in pointing to this as the primary and fundamental lesion. (13) Contracted fields and central or paracentral scotomas are usually present. (14) Treatment should include early neutralization by alkalis, and elimination by lavage, emetics, diaphoretics, and rapid oxidation, together with stimulation of the optic nerve by negative galvanism applied directly to the eye. Thyroid extract and pituitary extract may be indicated. (15) The manufacture and sale of wood alcohol should be prohibited or regulated by law. (16) If sales are permitted, safeguards and warnings should be required and the public instructed as to the great danger to vision and life. (17) A special revenue tax with registered "poison sales" would regulate and record its distribution, and in cases of poisoning reveal the source. (18) This tax should equalize the cost of denatured alcohol and methyl alcohol, and thus remove the temptation to adulteration because of cheapness. (19) All wines, whiskeys, toilet articles, and "patent medicines" imported from foreign countries should be tested for wood alcohol before passing through the customs inspection. (20) The name "methanol" specifically designates this product and yet avoids the tempting suggestiveness of the word "alcohol."

7. The Counting of Blood Cells and Bacteria: A Precise and Simple Method without a Special Chamber.—Georges Dreyer presents a modification of Wright's method for counting blood cells and bacteria by which he has overcome the lack of precision in that method. This he has accomplished by substituting hen's erythocytes, with their distinctive appearance, for human red cells as the standard suspension; by preparing them in such a way that they form a stable, unchanging standard suspension; by enumerating the standard suspension with great precision in an accurate counting chamber; by mixing standard suspension in measured proportion with the suspension to be enumerated, and counting them in the wet state. In this way a very accurate method for the enumeration of human red cells and bacteria is achieved without sacrificing any of the rapidity of Wright's technic. Figures are given of comparative blood counts by this method with those made with a first-class Bürker chamber, which show very slight differences between the two methods and what differences there are speak in favor of the differential method. The method is much quicker and less fatiguing than the counting chamber, and is equally available for counting erythrocytes, leucocytes, and bacteria.

2. Spina Bifida.—Frederick C. Pybus describes the various forms of spina bifida, which he says occurs in about one in 1000 births. It is met with almost equally in the sexes, and occasionally it is met with as family defect. Only a comparatively small number of cases admit of surgical treatment, which should be limited to the most favorable types, and those who, after operation, are likely and capable of becoming useful members of society. In spina bifida occulta operation is rarely required for the spinal defect, though it may be required for the relief of symptoms due to pressure or traction on the spinal cord. In larger defects where static deformity shows itself some form of spinal brace may be necessary or a plastic operation to control this. In all other cases general rules for the care of the patient may be given. It is important to keep the affected parts clean and the surface of the tumor protected from pressure and abrasion by a careful arrangement of wool around it, and its surface covered by an antiseptic dressing. The lower margin of such dressing may be sealed down by collodion or strapping, and so protected from the napkin area. Most meningoceles require operation, but there is no urgency; the operation may be carried out at leisure any time during the first year. Operation is contraindicated in the presence of hydrocephalus, as after operation the head continues to distend, the cerebrospinal fluid being robbed of a second outlet for the relief of tension. Other cases presenting gross bodily deformity should be included in this group. Cases in which operation is of doubtful use are those of myeloceles and meningo-myeloceles where there is a large raw area. The operation for the correction of spina bifida consists in isolation of the neck of the sac, freeing the spinal cord, and returning it with its nerves to the spinal canal. In some cases it is impossible to pack the cord back into the spinal canal. In these cases it must be left projecting as far as necessary with the hope that with growth in length of the spine it will be gradually drawn into its proper place. After replacing the cord the spinal defect is repaired, being careful to give sufficient protection to the cord and to prevent further displacement of the contents of the canal. In some cases osteoplastic repair may be necessary, though it has not been so in the writer's cases. Where a considerable defect requires filling, bone grafting, after the Albee method, would be suitable.

4. A New Method of Investigating Gastrointestinal Secretion.—E. C. Dodds, by taking samples of alveolar air at intervals after a meal, has been able to demonstrate that the tension of carbon dioxide undergoes certain definite changes in response to the amount of secretion poured out by the stomach and the lower portions of the alimentary tract. In later work, in conjunction with Dr. T. Izod Bennett, it has been shown that in normal individuals of varying type the curve of alveolar carbon dioxide tension so obtained corresponded closely with the curve of secretion of gastric hydrochloric acid. The variation in the tension of the alveolar carbon dioxide is explained in the following way: When acid is removed from the blood during gastric secretion the reaction of the blood tends to shift to the alkaline side. This shifting is prevented by retention of the volatile acid, carbon dioxide, the tension of which rises in the blood, and hence in the alveolar air. Later, when the alkaline intestinal and pancreatic secretions are poured out, the reaction of

the blood tends to shift to the acid side, and hence acid in the form of carbon dioxide must be eliminated. This is brought about by a lowering of the carbon dioxide tension in the blood, and therefore in the alveolar air. This method has been applied in a number of pathological conditions. The samples of air were collected by the Haldane-Priestley method, and the analysis made with the Haldane gas analysis apparatus. The writer claims the following advantages for this method over other methods in use: (1) The analysis of the alveolar air does not cause the subject any discomfort whatever, hence it may be employed in patients in whom nervousness, or some other general condition, forbids the passage of stomach tubes of any type. It is difficult to believe that in patients in whom the stomach tube and test meal cause considerable discomfort digestion follows its usual course. (2) The method gives an index of the total amount of acid or alkali being secreted from the blood by the gastric or other digestive glands, and hence is independent of neutralizing factors such as mucous and regurgitation which affect ordinary gastric analyses. (3) It gives a measure of secretory activity below the pylorus, as well as of that of the stomach. (4) The form of test meal is immaterial provided that a fixed standard be selected, allowing comparisons with the curve shown by normal persons after the same meal.

1. Renal Efficiency Tests.—Hugh Maclean gives his personal experience with renal function tests that he has been using for several years. While no tests for renal efficiency are necessary in well-marked acute nephritis, certain tests may be necessary late in order to ascertain what progress is being made, and here functional tests are quite as important as, if not more important than, clinical symptoms. In his routine work Maclean estimates the blood urea, and has never obtained any additional information from an estimation of the nonprotein nitrogen as well. As a result of a large number of experiments he has found that the blood of normal individuals may contain from 15 to 40 mg. urea per 100 c.c. blood. In young people the normal content lies toward the lower level, and perhaps the maximum should be placed somewhere below 30 mg. Anything above 45 mg. is suspicious. While this test is of great value in many cases, it unfortunately gives no indication of any kidney defect in subacute and chronic cases of Bright's disease until the greater part of the renal tissue is out of action. A point to note is that lowering of the blood urea is not necessarily any indication of improvement unless the patient continues on the same kind of diet as he had when the blood urea was found to be high. This unfortunately is frequently forgotten. On the whole the estimation of urea or nonprotein nitrogen in the blood is one of the best tests we have for advanced renal deficiency. General speaking, the diastatic test is of value in conjunction with other tests, but should never be relied on alone. Undoubtedly the phenolsulphonephthalein test often seems to give a fairly good indication of the state of the kidneys, but in the writer's experience the results have not been very satisfactory. The same may be said of the indigo-carmine test. As the result of using the "urea concentration" test in over 10,000 patients suffering from various grades of nephritis it may safely be said that it is exceedingly useful as a simple means of ascertaining the state of the kidneys. If the test shows a concentration of urea over 2.5 or 3 per cent., it is quite certain that the kidneys are efficient. Of all the procedures used in renal investigations from the clinical side, this simple procedure appears to give more information in the majority of cases than any other. For practical clinical purposes Ambard's coefficient of urea excretion is too elaborate to be of value. A good deal of useful information may be obtained by comparing the concentration of the urea in the blood at a given time with that in the urine secreted over a short time. The retention of sodium chloride in the system is at once indicated by the presence of edema, so that it is practically never necessary to perform a test for salt tolerance. If no edema is present we may be certain that salt is excreted all right. This observation is important because it is no uncommon occurrence for nephritis patients to be limited to salt-free diets where no edema exists. From the clinical standpoint we do not need any more tests for ascertaining the state of renal function. We have too many already. What is needed is some simple combination of tests which will give the necessary information, and which all physicians can use with a view to increasing our knowledge of their value. Such a scheme for examining a renal case includes: (1) Estimation of blood urea or nonprotein nitrogen; (2) examination of 24-hour specimen for protein, casts, blood, pus, etc., and estimation of diastatic activity; (3) urea concentration test; (4) condition of cardiovascular system; (5) presence or absence of edema; (6) general condition of the patient. Modern renal tests are important in surgical work, especially in certain genitourinary diseases such as enlarged prostate.

6. Acute Ileocolitis in Infancy.—M. S. Picard states that in the treatment of ileocolitis in children specific therapy has had no success in his hands. He believes as many children die from starvation as from the disease. Children are fed over long periods on rice water, barley water, broths, and liquid peptonoids, foods of low caloric value, until their tolerance of food has sunk so low that assimilative power is gone. The therapy consists in a thorough emptying of the bowel. The remedy of election is castor oil. Calomel should not be used in the inception of the disease. All efforts should be made to keep the water balance. The habit of giving a child water by spoon or a medicine dropper is too uncertain. Water in large quantities should be administered through the nasal tube. If vomiting is uncontrollable saline solution is given intraperitoneally. The writer claims to have saved almost hopeless cases by this method. Normal saline or 5 to 10 per cent. glucose can be used, 8 to 12 ounces, or even more, being given. He has seen no harmful effects except that frequently the tendency is to wait too late. Drugs are of no value in shortening the course or modifying the type of the disease. He has abandoned the use of opium and of irrigations aside from flushing the first day. Since abandoning irrigation he has seldom had to treat tenesmus, which without irrigation disappears about the third or fourth day. He particularly emphasizes the importance of avoiding starvation, and treats the condition as in typhoid fever, using forced feeding if necessary. He finds protein harmless and cocoa and junket the main reliance during the early days of the disease. The child is fed every four hours. At 6

o'clock, cocoa; 10 o'clock, cocoa and junket; 2 o'clock, broth and scraped beef; 6 o'clock, cocoa and junket; 10 o'clock, cocoa.

2. Some Observations on the Fractional Analysis of the Gastric Contents.—Julius Friedenwald and Zachariah R. Morgan, from their study of 210 cases in which fractional analyses were made, believe the following conclusions may be safely drawn: (1) By means of fractional analyses the entire cycle of digestion can be studied, both as to the secretory and motor activity of the stomach. (2) By complete aspiration at any period of digestion one can obtain definite information regarding the amount of secretion. (3) In duodenal ulcer the acidity is usually higher than in any other condition. There is a rapid and prolonged rise, followed frequently by a fall, and a secondary rise, though there may be a continuous prolonged rise from the onset. The highest acidity appears frequently after an hour. Blood is at times found in the contents, which adds additional evidence as to the presence of ulcer. Rapid evacuation is rather characteristic of uncomplicated forms of duodenal ulcer. (4) In gastric ulcer there is no typical curve of acidity, though a fall followed by a secondary rise is frequent. There is usually delayed motility in gastric ulcer. (5) By means of fractional analyses the acidity in any period of the cycle of digestion may be noted. The highest acidity frequently occurs after an hour and occasionally before, so that the appearance would be entirely overlooked should reliance be placed entirely upon the hour extraction. (6) The effect of an ulcer cure upon the hyperacid secretion can be followed by means of fractional analysis. In but half the cases, however, is a decided reduction in acidity obtained even though clinical improvement may be noted, indicating that the symptoms ordinarily attributed to excess of acid are not necessarily due to this factor. (7) In pyloric stenosis there is usually a higher acidity during the whole period of digestion, with delayed motility. Food shreds are observed in the fasting state. (8) In most cases of gastric carcinoma one finds a typical achylia frequently with delayed motility, and a rather high total acidity, with lactic acid and blood. The Wolff-Junghans test is positive, considerable amounts of albumin being present within three-quarters of an hour, being markedly increased within an hour to an hour and a half. (9) Cases of chronic gastritis present the same characteristics as are usually observed in simple achylias. The total acidity is usually higher, however, and in addition mucus is obtained. The motility of the stomach is often delayed. (10) In gastric syphilis the curves of acidity are similar to those observed in cancer. The total acidity is high, and there is a complete achylia; the stomach emptying itself rapidly. (11) Fractional analysis of the gastric secretion according to the Rehfuss method is extremely important in all cases of achylia gastrica, inasmuch as by means of this method one can easily differentiate the true achylias from the spurious forms. In the true achylias free hydrochloric acid is absent in every specimen; the total acidity is low, and there is a marked hypermotility. In pernicious anemia one observes the typical features of a true achylia. (12) In nervous gastric affections one observes the various forms of hyper- or hypochlorhydria, or normal acidity. The hyperchlorhydrias present a rapid rise in acidity 100 or over with a normal motility. One frequently notes among these cases the so-called false achylias, with an absence of free hydrochloric acid at the end of an hour, yet presenting a hyperacidity before or after this period. (13) In gall-bladder affections one observed a tendency to a lowered acidity and achylia, while in chronic appendicitis hyperacidity is usually observed. (14) While fractional analyses are of the greatest importance and usually present, additional evidence in diagnosis, a study of this series of cases, together with the observations of Rehfuss, leads the writers to the conclusion that no pathognomonic curve exists which can be considered as absolutely distinctive of any gastric affection.

Direct Bronchoscopic Extraction of Foreign Bodies.—Dr. Castilho Marcondes relates a personal case of extraction of a foreign body from a bronchus, and gives a brief résumé of the entire subject before and after the pioneer work of Killian. The patient was a 5-year-old child, and the foreign body, a seed, had been in the bronchus for more than a month. The degree of success was complete, and the intervention was witnessed by a large number of the best-known medical men in Rio. Others in Brazil who have had similar experience comprise Meira of Rio, who recently reported a case before the National Academy of Medicine, and Seng, a well-known operating surgeon of São Paulo, who has recently had two cases, in both of which the outcome was all that could be desired. The author has evidently had other cases, but Brazil does not seem to have the record of Argentina, in which country these extractions have been rapidly increasing of late years. Professor Segura of Buenos Aires, like some of his northern contemporaries, already has a small museum of extracted foreign bodies.

Treatment of Putrid Affections of the Lung with Neosalvarsan.—Savolin states that salvarsan has been used for pulmonary gangrene since 1914. First introduced into practice by Brauer, the latter was followed by O. Gross, who reported six cases in 1916, while three years later Schroeder extended the use of the remedy (neosalvarsan) to putrid bronchitis. The author has had one case each of pulmonary gangrene and fetid bronchitis. In all of the cases mentioned the results were good—either complete cures or improvements.

Artificial Inflation of the Stomach and the Diagnosis of Operability of Cancer.—Faltin refers to the original method of Runeberg in 1884 of inflating the stomach in connection with the diagnosis of cancer. This has been used in his clinic as a routine measure for a number of years, and has been found of great value in determining operability or inoperability. The greater the distensibility of the stomach, irrespective of the recognition of cancer, the better the outlook for a radical operation. If the stomach does not inflate the latter is nearly out of the question. In pyloric insufficiency the test is vitiated, because the insufflated air escapes at once into the duodenum. This occurrence is in itself a bad prognostic, even if the neoplasm cannot be palpated. Usually it signifies that much of the gastric wall is rigidly infiltrated. It is very unusual to operate on such a stomach after laparotomy. The use of this method has lowered the frequency of surprises after the stomach has been exposed. It cannot, of course, replace the *x*-ray, but in the absence of the latter is, as stated, very valuable.

Book Reviews.

RATIONAL TREATMENT OF PULMONARY TUBERCULOSIS, by CHARLES SABOURIN, M.D., Medical Director of the Durtol Sanatorium, Puy-de-Dome, France; Sixth edition, 1921, 440 pages. Price, $3.50, net. Philadelphia: F. A. Davis Company.

SABOURIN was one of the pioneers of the sanatorium treatment in France, and his book is a welcome addition to the therapeutics of pulmonary tuberculosis. The name of the translator has not been given. Had he been an American physician he probably would have omitted the first chapter, which is devoted to a discussion of the difference between *tuberculosis* and *phthisis* and its respective designation. The American physician designates the disease due to the tubercle bacillus as tuberculosis, adds the word pulmonary if there is an involvement of the lungs, divides the disease into first, second and third stages, and hardly ever uses the term phthisis or phthisis pulmonalis. Even among the laity the term tuberculosis has become so familiar that even the word consumption is coming into disuse.

The second and third chapters in part I of the book are devoted to the "acquisition" of tuberculosis and to congenital immunity respectively. In chapter IV the author very wisely calls attention to the fact that it is erroneous to believe that tuberculosis becomes implanted almost exclusively in the apices of the lungs. He says that in early childhood the initial focus of the disease is most frequently situated in the central portions of the lower lobes and accompanied by enlarged lymphatic glands. He admits, however, that such a condition can only be diagnosed by the *x*-ray, and later on he freely states that in the adult as well as in the child, clinically, the disease process at the apices is the first to become perceptible to examination and consequently remains the first outward manifestation of tuberculosis of the lungs.

When speaking of the mortality, he gives us the sad figures that 150,000 deaths occur annually in France. The need of early diagnosis in tuberculosis is well set forth in strong and forceful language. In a chapter, entitled "Fundamental Features of the Rational Treatment of Tuberculosis," he gives creosote the first place, although he does not speak very enthusiastically about it, and he considers it, as well as arsenic and the various phosphates, as mere tonics. He strongly opposes the administration of tannin in high fever, which is a favorite custom with many French physicians. Concerning tuberculin he very cautiously makes the following statement: "Some high medical authorities attribute a certain number of recoveries to the tuberculins. It is to be hoped that these favorable results will be confirmed with sufficient frequency to carry conviction and elevate this method of treatment from the state of hesitation in which it is at present."

Deploring the custom of well-to-do European patients to spend the winter in southern resorts and the summer in winter resorts, he comes to the conclusion that the main factors are pure air by day and by night, the avoidance of physical and mental fatigue, and wholesome generous diet. By this, however, he does not wish it to be understood that he favors overfeeding. The author devotes quite an interesting chapter to the subject of auxiliary treatment under which he classifies the dry or wet rub, baths, true hydrotherapy, and counterirritants. He pays a great deal of attention to the matter of skin hygiene and skin affections, a subject which one finds very rarely treated in works on tuberculosis. Acne, and particularly the necrotic type, he treats by early cauterization, pityriasis, seborrhea, keloids, or ichthyosis, and for the many other skin affections occasionally observed in the tuberculous, he cites suitable remedies; even for alopecia he gives a prescription consisting of a local application, its principal ingredient being pilocarpine:

"R	Aquæ coloniensis....	150 gm.	(5 ounces)
	Tincturæ cantharidid	8 gm.	(2 drams)
	Glycerini puri.....	2 gm.	(½ dram)
	Pilocarpinæ nitratis.	0.8 gm.	(12 grains) MS.

"A toothbrush is slightly moistened with this solution and the roots of the hair over a surface of the size of the palm brushed over with it each day, the entire scalp being thus gone over in a week's time."

The rest of the volume is devoted to the symptomatic treatment, the tuberculosis sanatorium regime and the utility of sanatoria. The author does not offer anything new, but these chapters merit the careful perusal by the students of tuberculosis as well as sociologists, because they contain discussions of the following subjects: Sanatoria for the wealthy and for the poor; social hygiene; tuberculosis and marriage; tuberculosis and child welfare; and phthisiophobia and phthisiomania. As a whole the book can be recommended to the careful persual of all interested in the rational treatment of tuberculosis. If any criticism is justified, it is that the translator who has resorted to some rather queer expressions, has evidently failed at times to grasp, or at least to give the exact meaning of the French author.

THE ASSESSMENT OF PHYSICAL FITNESS. By Correlation of Vital Capacity and Certain Measurements of the Body. By GEORGES DREYER, C.B.E., M.A., M.D. Fellow of Lincoln College, Professor of Pathology in the University of Oxford, Corresponding Member of the Royal Danish Academy of Letters and Sciences, in collaboration with GEORGE FULFORD HANSON, late Lieutenant U. S. A. Medical Corps, Air Service, with a foreword by CHARLES H. MAYO, M.D., Rochester, Minn. Containing 127 pages with tables and illustrations. Price, $3.50. New York: Paul B. Hoeber, 1921.

DOCTOR Dreyer's book on "The Assessment of Physical Fitness" offers an extremely interesting thesis; but the fundamental concept underlying the tables presented in this small volume cannot be accepted without immediate challenge.

Topinard beautifully expressed an anthropological truth when he said that any three measures repeated in a large series of cases will give information of anthropological value; so that Doctor Dreyer's table, based on the relation between the weight of the human body and the sitting height of the trunk, the circumference of the chest, and the vital capacity of the lungs, can at least claim Topinard's dictum as a precedent.

We find the statement that there are separate tables for males and for females. "Such a division is essential because the two sexes differ greatly in almost every particular, and the results obtained by using the tables for one sex in the case of the other are found to be entirely misleading." One might surmise from these teachings that the female anatomical structure is basically different from that of the male. Such a teaching is fundamentally contrary to the revelations brought out by anthropological studies; for the mammal is an evolutionary type in which there is a cogent relation in the scheme of development of the child, the female and the male. Gratiolet first mentioned this possibility, and subsequent anthropological investigations wholly substantiate Gratiolet's contention.

Doctor Dreyer's book gives many pages of figures dealing with the "normal;" but it signally fails anywhere to indicate or to define by what standards the normal is measured other than the collection of a vast number of statistical measures. There is no indication that any cognizance is taken at all of the cogent facts that anthropology, endocrinology, psychiatry, and other sciences daily teach us, namely, that the relation existing between the child, the feminine, and the masculine morphology is infinitely deeper rooted than the superficially observed differences. It is difficult to determine why a new and arbitrary branch of anthropology should be created. Far better would it be if physicians would inquire into a science that has been established since 1875, and before, and make their studies in accordance with a precedent that has been set by anatomists, physicians, and anthropologists since the days of Broca, Quatrefages, Topinard, and the immortal Morton of our own country. If anthropology offers aid to the clinician, and it does, then we should first study anthropology and subsequently apply it to our clinical problems; and if we study anthropology, then Doctor Dreyer's book justly loses its value.

Society Reports.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Forty-Third Annual Congress, Held in Atlantic City, May 30 to June 1, 1921.

THE PRESIDENT, DR. HARRIS P. MOSHER OF BOSTON, IN THE CHAIR.

President's Address: The Liver Tunnel and Cardiospasm.—Dr. HARRIS P. MOSHER of Boston delivered this address, in which he recalled that last year he had reported the cadaver findings in thirty casts of the injected esophagus and stomach of adults and those of sixty injected and dissected babies. The findings now presented supplemented these. The result of his observations indicated that a free passage through the subdiaphragmatic esophagus depended upon the patency of the liver tunnel. In ten cases of cardiospasm in which he had sufficient data to draw conclusions there was either a partial crescentic stricture, or a full annular stricture at the beginning of the liver tunnel and opposite the upper edge of the left lobe of the liver. In his cases stricture and not spasm was found to be the chief causative factor. More cases were necessary, however, in order to determine whether or not the high percentage of stricture in cardiospasm which he had found was constant. The basic fact in his paper of last year was that the liver was chiefly responsible for the shape of the lower end of the esophagus. The subdiaphragmatic portion of the esophagus ran in a tunnel of liver, and according to the closeness of the investing liver was either flaring and trumpet shaped or narrow and cone shaped. *X*-ray plates of the lower end of the esophagus often showed it ending in a nipple-like point. Between this and the fundus of the stomach there was a gap, which was the closed liver tunnel. The upper edge of the liver often made a crease in the front wall of the esophagus, and this crease was present at birth. The left crus made a crease in the posterior wall of the esophagus and a marked notch in its left edge. Experiments on the cadaver showed that the crescentic mound which was often seen through the esophagoscope in the right half of the field as the liver was approached was made by the upper rim of the liver. The result of observations made by Dr. Gordon of the *x*-ray department of the Massachusetts General Hospital, in collaboration with the writer, showed that in a majority of normal cases there was an appreciable delay of the bismuth milk at the upper border of the liver when a patient swallowed. Dr. Gordon made the further observation that when the diaphragm was lowered the bismuth milk which was held back momentarily by the liver edge, shot at once into the stomach. He had found in the cadaver four specimens of annular stricture of the lower part of the esophagus. Each one capped circumscribed dilatation of the esophagus which was bounded below by the constriction caused by the left crus, and each one was on a level with the upper edge of the left lobe of the liver. Of three cases of cardiospasm of which he had good records the diaphragm was moderately lowered in one and markedly lowered in the other two. In grouping his cases of cardiospasm he found there was an element of stricture in the majority of them and this stricture was by preference at the beginning of the liver tunnel at the upper edge of the liver. The stricture element in his cases varied from a slight crescentic fold in the right quadrant of the esophagoscope in the region of the hiatus to a full annular stricture with a central opening. In the cases which showed the crescentic fold steady pressure with the end of the esophagoscope usually resulted in the tube slipping by into the normal esophagus below and through this into the stomach. The withdrawal of the tube disclosed a vertical slit in the mucous membrane of the esophagus. He held these cases to be analogous to partial webs at the mouth of the esophagus. He had records of three cases in which there was a full stricture with a central opening. This stricture was at the upper edge of the liver. He had had one case which showed a narrowing of the whole length of the liver tunnel. One might, then, have a narrowing of the whole length of the liver tunnel or of any part of it. Observation seemed to show that spasm was a minor element in these cases. He believed these structures were due to some inflammatory process either within the liver tunnel or in the vicinity of the cone of the diaphragm. The inflammation could originate in any part of the peritoneal cavity, and when the lesser omentum became involved the liver tunnel became less flexible, the liver and diaphragm less mobile, and the familiar result, temporary cardiospasm, followed. In one of his cases of full stricture the patient when an infant swallowed a two-cent piece. In another case there was a history of general peritonitis twenty years ago. He had proved to his satisfaction that many of these so-called cases of cardiospasm were mainly cases of stricture of the upper end of the liver tunnel.

Tonsillectomies in Adults for Rheumatism with Critical Review of Reviews.—Dr. HILL HASTINGS of Los Angeles read this paper, in which he stated that comparatively little had appeared in the laryngological literature dealing with the clinical problems of tonsillectomy or the results from the patient's standpoint. In the present paper all adult cases in which tonsillectomies were done solely for ear, nose, and throat conditions were excluded; also cases that dated back over six years, and all cases that were of shorter duration of observation than four months. Tables were presented showing ages, duration of rheumatism, parts affected, character of rheumatism, with results of tonsillectomy, throat history, and subsequent history of 130 cases. The subsequent results were based on personal examination of the patient by the writer, by the internist, or by the orthopedist, and checked up by questionnaires received from all of the 130 cases except 26 who could not be located. Of these, 39.5 per cent. were improved, some were gradually growing worse, some were remaining stationary. In this whole series of tonsillectomies there were no hopeless chronic cases operated upon, and it would seem that the percentage of non-improved, 21 per cent., should not have been so high; nevertheless many of these cases that were marked "unimproved" might have become hopelessly chronic but for the tonsil surgery. Of the 40 cases in which apparent cure resulted, 22 were diagnosed "chronic arthritis, mild"; 11 were acute arthritis cases, and three were diagnosed "myalgia." A general survey of the history of these patients showed that most of them had suffered for years, but not continuously, with pain and stiffness in one or several joints. A few of them gave a history of symptoms of tonsil trouble; some gave no history of throat trouble. In seven cases the history showed an acute tonsillitis as a forerunner of the rheumatism. In other cases an accumulation in a tonsil crypt caused rheumatic symptoms. It had been the writer's experience to find that adult patients suffering from toxic symptoms were referred to the laryngologist for his decision as to whether or not the tonsil was the seat of a chronic infection. Other patients came with the statement that their tonsils had been pronounced infected. The writer told such patients that every adult tonsil was a chronic infected tonsil from which a positive culture could be made. The same was true of most tonsils in children. Therefore, the necessity for a tonsillectomy depended not solely upon the examination by a laryngologist but upon a complete study of the patient to determine all possible factors for the invalidism.

Results of the Treatment by X-Ray and Radium of Diseased Tonsils and Adenoids.—Dr. D. BRYSON DELAVAN of New York presented this communication, in which he said that very small amounts of *x*-ray were sufficient for the reduction of lymphoid tissue, doses so small that no injury, it was claimed, resulted to other parts from its application. The current used was too weak to affect even the external integument, but sufficiently strong nevertheless to destroy the lymphoid tissue, and no scar tissue was left behind. The rays themselves did not destroy bacteria, hence they did not affect concealed abscesses of the tissue. They acted by so modifying the crypts that free drainage from them was secured, and thus the crypts continued to empty themselves of all offending contents. As the tonsil atrophied the infection disappeared from the opening up and drainage of the crypts. Dr. Murphy maintained that little atrophy would result in the

case of fibrous tonsils, since the rays had no effect upon fibrous tissue. This being true such cases must continue to be treated surgically, as heretofore. Moreover, since radiation did not affect bacteria, its application in cases of concealed chronic abscesses of the tonsil would be ineffective, an unfortunate circumstance in view of the prevalence of this condition. That the method of treatment by radiation would quickly come into general use was improbable. The region of the neck was one containing numerous important anatomical structures which must be carefully guarded against injury. Inasmuch as a knowledge of the safe and effective use of both *x*-ray and radium was acquired only through highly intelligent study and much experience, it was far better that experiments be carried out by those qualified for the work than that the success of a method of such good promise should be compromised and perhaps discredited through errors due to incomplete understanding of the medium or to faulty technique in its application. Knowledge of this subject was in its infancy, and far more study and observation was needed to prove the value of the theories already suggested. What had been done had developed questions of the greatest interest, not to be settled by theoretical discussion but by painstaking experimentation and accurate scientific observation.

Must It Always Be Tonsillectomy?—Dr. HENRY L. SWAIN of New Haven, Conn., read this paper, in which he said that in late years the tonsil had been looked upon as the cause of an astonishingly large number of diseases and symptoms affecting the comfort and menacing the lives of patients, and while recognizing the perfectly laudable desire on the part of the operator to get rid of the tonsil, root and branch, he felt that we as a profession ought not to leave out of consideration the fact that there were other methods than tonsillectomy, which were safe, sane, sure, and enduring in their results. These methods did not endanger life, did not subject the patient to the distressing effects of serious hemorrhage, avoided the chances of lung abscess, and brought the patient through the ordeal with undistorted and non-adherent palate, and without the disturbance of the daily routine of his life. By a simple method of slitting up intercommunicating crypts and other retention pockets, punching out undesirable tissue areas, and, if necessary, shrinking the tonsils by galvanocautery procedures, he was able, by the same process, to prove tonsils guilty and to make them cease from troubling. He frequently achieved as spectacular and permanent results thereby as he or anybody else ever attained by perfect tonsillectomies. Many others had had similar results by other means; only lately he had been made acquainted with the brilliant results of *x*-ray exposures. He felt convinced that it was not always necessary to do a complete tonsillectomy in order to remove the threat and menace of the faucial tonsil.

Dr. JOSEPH L. GOODALE of Boston, Mass., asked Dr. Hastings to tell them if in these cases it was possible for him to ascertain absolutely whether there had been an unusually large proportion of what might be called anaphylactic types among the 20 per cent. of arthritic cases that failed to show improvement. He asked this because Dr. Hastings suggested the hypothesis that certain arthritic cases might conceivably be explained on the ground of previous sensitization of the joints, which, in subsequent infection, were again brought into prominence—not through direct penetration of bacteria but through toxins generated in the tonsils finding response in the joints. Dr. Goodale said he had seen a case of what he had called ingestion anaphylaxis giving rise to arthritis. In this case the patient gave up the foods that had been demonstrated to be the cause of anaphylaxis, the joint symptoms disappeared, and he had been well ever since. In regard to Dr Delavan's paper, the cases that could be influenced by *x*-ray were chiefly the juvenile ones; in the senile ones, with symptoms resulting from absorption, he questioned whether one could accomplish so much.

Dr. JOSEPH BRYAN of Washington, D. C., stated his experience was confined to five or six cases, three of which he reported. One of these was a patient who following an attack of influenza developed pneumonia with endocarditis and nephritis. The latter condition persisted long after the other complication had cleared up. The tonsils showed the presence of two kinds of streptococci, *viridans* and *hemolyticus*. The patient received six applications of *x*-ray when the nephritis cleared up, though the organisms in the tonsils remained the same. In a second case with marked *Streptococcus hemolyticus* infection *x*-ray treatment had effected no reduction in the amount of tonsillar tissue, the organisms were as numerous as before, and the patient showed no improvement. The third case was that of a woman of 73 with glaucoma and infected tonsils containing *Streptococcus hemolyticus* and *viridans*. The *x*-ray was applied and the tonsils had been completely absorbed. The organism had been changed from *viridans* to *hemolyticus*. There had been great improvement in her health and in her eye. The *x*-rays were a valuable adjunct to treatment, particularly in selected cases, but he did not believe they would supplant surgery.

Dr. CORNELIUS G. COAKLEY of New York said about ten days ago he had reported before the New York Academy of Medicine the results of a survey of tonsils that he and his associates had operated upon during the past twelve years for rheumatism, and their results in the series of 146 cases were above 85 per cent. of very marked improvement or cure. The total time consumed in giving the *x*-ray treatment was certainly more per individual patient than when surgery was employed. There was no question that the *x*-ray would reduce the size of lymphoid tissue. The question came up, "What effect will simply reducing the size of the tissue have on the infective material?" The Rockefeller Institute had cultured the tonsils before and after *x*-ray treatment, and found various organisms before and also afterwards. Dr. Coakley said he thought it would also be found eventually that the *x*-ray would unquestionably reduce the size of the tonsils, but whether it would put the tonsils in such a shape as to free them from infection, especially in the case of small-sized tonsils, he had great doubt.

Dr. LEWIS A. COFFIN of New York asserted that the tonsil had nothing at all to do with the trouble. The trouble was altogether with those tonsils that did not free themselves of pus or crypt secretion and accumulation. The problem of the tonsil was solved if the crypts were thoroughly drained or rendered aseptic. The interesting questions were why some tonsils developed so as to interfere with their own drainage, and whether one could do anything to prevent such development.

Dr. J. PAYSON CLARK of Boston, Mass., reported a case of severe rheumatism in a woman, 69 years of age, who was greatly relieved by tonsillectomy. Two years after the operation she stated that she was free from pain and could walk with more ease. Slitting the tonsils was, of course, a procedure which had been successful in the hands of many of them. Suction in the crypts he thought a valuable treatment in suitable cases.

Dr. GEORGE L. RICHARDS of Fall River, Mass., asked Dr. Delavan to tell them about the tendency of dryness of the mouth and throat following *x*-ray treatment. Even with ordinary tonsillectomies there was a certain amount of dryness of the mouth and throat in a certain percentage of cases. There was no doubt that the *x*-ray would destroy lymphatic tissue, but was it not possible that in this destruction we should have ill results, not in a year, but in some later period?

Dr. HARMON SMITH of New York pointed out that they all knew that in the application of the *x*-ray and radium they benefited a malignant tumor by the production of endarteritis. The application did not destroy the tumor; it shut off the blood supply and shrunk the mass. When this happened nature established a new blood supply of more lasting character, and the tumor began to grow again. When, in the application of raying, the lymphatic tissue was not destroyed, but the blood supply shut off, the tissue shrunk; when the blood supply began to reestablish itself, as it would if the patient lived long enough, there would be an increased growth of the mass.

Dr. JOHN R. WINSLOW of Baltimore, Md., said we had proof that *x*-ray and radium would destroy tissue, lymphoid tissue included, but what proof had we that it would not destroy more important structures in the

neck? If it would destroy these tissues, why should it not destroy other tissues (the parathyroids, for instance)? In applying the *x*-ray to the nasopharynx he thought there was a certain possibility of the production of meningitis. In fact this had occurred in the treatment of tumors in this region with radium. In the treatment of comparatively simple hypertrophy, such as that of the tonsils and adenoids, he did not think that the time element was much reduced or that the safety was much greater as compared with surgery.

Dr. HASTINGS of Los Angeles, in closing his part of the discussion, emphasized the importance of studying one's cases thoroughly before deciding for or against operation. It would be interesting to study those cases which were not operated upon to see if secondary focal symptoms developed. It would also be interesting to study a group of cardiovascular cases in the way in which this group of rheumatic cases were studied. Dr. Goodale asked whether there had been any anaphylactic reactions noticed in the uncured cases. The speaker's attention was not brought to such reactions, though such might have been the factor in the case reported in which the patient starved himself for twenty-six days on account of rheumatism with marked improvement, the symptoms recurring when he began to eat.

Dr. DELAVAN of New York called attention to the fact that he had not said anything that should lead one to suppose that he accepted all the proposition about radium in this connection. On the contrary, his idea was to bring up the subject with as much conservatism as possible and to point out the cases in which it was probably of benefit. It had been demonstrated that this form of treatment would probably rather diminish lymphoid tissue, and that it would not do other things. He thought they should receive what was given them with friendly consideration, and try to find whether there was anything of practical value in the method. Valuable deductions would not be reached through the medium of theoretical objections or unkind opposition. When scientific tests had been made they might be given to the world, and then we would know more.

Dr. SWAIN of New Haven, Conn., in closing the discussion, said he had worked a good deal on what he had presented. It had been conscientiously done so that he was able to assure them that there were several safe ways to eliminate the tonsil as a cause of trouble. He agreed with Dr. Hastings that we must in considering these focal infection cases remember that we had twenty-six feet of intestines of which the tonsil was only the beginning.

Ventriculocordectomy—A New Operation for the Cure of Goitrous Paralytic Laryngeal Stenosis.—Dr. CHEVALIER JACKSON of Philadelphia presented this communication, in which he stated that in ventriculocordectomy he believed we had a simple endoscopic operation that could be done under local anesthesia and that would cure almost every case of laryngeal stenosis due solely to abductor paralysis if the case was not complicated by a faulty tracheotomy. The technique of the operation was as follows: In children no anesthetic, general or local, was used. In adults cocaine was painted on with a swab and one-quarter of a grain of morphine was given an hour before operation. The larynx was exposed with the direct laryngoscope and through it the punch forceps was inserted. The ventricular band was elevated and the forceps applied. Thus the floor of the ventricle and part of the mucosa of its outer wall was removed at one clip. A clear cut was necessary. In some cases the ventricular bands were in tight apposition, so that the forceps had to be insinuated between them before expanding the jaws. Great care should be taken to avoid getting too far outward between the thyroid and cricoid cartilages lest the crycoarytenoideus lateralis be injured. With the forceps used this accident was easily avoided. Great care should be taken not to excise any part of the arytenoid cartilage. The clipping off of the extreme tip of the vocal process of the arytenoid was necessary in some of the cases because of the shortness of the cord, but the excision of more than this was unnecessary and should be avoided. Judging from post-graduate teaching at the Bronchoscopic Clinic, few laryngologists seemed to realize how far the vocal process of the arytenoid projected forward toward the anterior commisure. To perform the operation required education of the eye and the fingers in endoscopic technique. Of course, the excision of the cord and ventricular floor could be done by laryngofissure, but in this we had, though not a serious operation, one that would appear much more formidable to the patient. No after treatment was necessary. The surface of the wound was covered with an exudate under which healing by granulation progressed. The duration of the operation done endoscopically on one side only was never over one minute in any case, and in some cases healing was completed in ten days. Ventriculocordectomy was indicated in cases of stenosis resulting from a hopelessly paralyzed larynx. This or any other form of clearing the air-way was contraindicated in the first six months of abductor laryngeal paralysis. In most cases it was wise to wait a year. The best means of affording relief of dyspnea and safety of the patient during this waiting period was by prompt low tracheotomy. High tracheotomy was the cause of more cases of cicatricial laryngeal stenosis than any other one thing. With a low tracheotomy a pair of proper cannulæ and a daily toilet of the fistula nothing was lost by waiting. Out of eighteen cases ventriculocordectomized seven that were uncomplicated by cicatricial stenosis were afforded by this procedure alone satisfactory relief of dyspnea. Considered in the light of the degree of preservation of the functions of the larynx ventriculocordectomy, in the writer's opinion, surpassed any previously devised operation. It was ideal for those cases in which neural and muscular atrophy had rendered resumption of normal cordal motility hopeless by either spontaneous recovery or neuroplastic surgery.

Dr. D. BRYSON DELAVAN of New York stated that it was known that methods similar to this had been employed, not only in the surgery of the human being but in veterinary surgery. Any betterment in the process and what might be called standardization of the treatment was welcome.

Dr. ROBERT CLYDE LYNCH of New Orleans, La., said it struck him during Dr. Jackson's description of the reason for the regeneration of the vocal cord, that in cases of infrapharyngeal carcinoma which he had operated on by suspension, and in which he had removed a considerable portion of the vocal process of the arytenoid cartilage and muscle, there had been no effort on the part of nature to re-form any portion of the cord whatever. He was at a loss to know why this had occurred, since in cases of thyrotomy the cords did re-form or something re-formed which took the place of the vocal cords. In the cases he had operated on by intralaryngeal resection there had been no disposition to renew the cord. The space remained wide open. Possibly this might add something to the theory of the regeneration of the cord.

Dr. CORNELIUS G. COAKLEY of New York said that in his service at Bellevue they saw two or three of these cases a year. The only treatment they had been using was tracheotomy. Most of their cases were in patients with central lesions or bulbar paralysis. Dr. Coakley asked Dr. Jackson whether he considered it necessary in long-standing cases of bulbar paralysis to do a tracheotomy, and how much hemorrhage he got during the operation on small children.

Dr. JOSEPH B. GREENE of Asheville, N. C., said he had several patients under observation at the present time who should have treatment and he would refer them to Dr. Jackson.

Dr. HENRY L. SWAIN of New Haven, Conn., asked Dr. Jackson what proportion of cases had to have ventriculolcordectomy and what vocal results he obtained.

Dr. EMIL MAYER of New York asked Dr. Jackson what local anesthetic he used, and what was the manner of application and the strength of that particular local anesthetic.

Dr. CHEVALIER JACKSON of Philadelphia, in closing the discussion, said in regard to the matter of the voice that the patient must be told that the voice would be reduced to a whisper for quite a number of months. Then it would be a stage whisper, and later the patient would be able to phonate; in a year or so he would have a voice that could be heard across the room. The operation was especially adapted to the goiterous cases. Their expectation of life was longer than in other cases. In tabes and disseminated sclerosis it was not so long, although many survived for years. With regard to Dr.

Swain's question about the necessity of doing a double operation, after making a section on one side, usually about a month elapsed before he operated on the second cord. If the patient had plenty of air, the second cord might not need operation, but he would not feel justified in abandoning the tracheotomy cannula in that case. Regarding the name of the operation, ventriculocordectomy, the floor of the ventricle was excised, and that was why he used the term, faulty though it might seem. As to the anesthetic, 20 per cent. cocaine was sufficient in most cases. Most of the patients were adults; one was a child in whom no anesthetic was needed. With regard to preliminary tracheotomy, in the cases of bilateral paralysis in which one cord had become cadaveric, the patients would get along without tracheotomy. He felt that it was better to tracheotomize than to wait a year to see if movement would be recovered. If no motility appeared within a year, adduction would never come back and ventriculocordectomy was indicated. Regarding hemorrhage, it was extremely insignificant. Probably the pinching off of the blood vessels prevented hemorrhage.

Papilloma of the Larynx in Children with the Report of an Unusual Case.—Dr. O. A. M. McKIMMIE of Washington, D. C., read this paper, in which he stated that a review of the literature brought out the following facts: Our knowledge of the causation of papilloma had not increased; nearly all writers stated their conviction that removal by use of the direct laryngoscope was the preferable method if removal seemed best. The youngest children operated upon by the direct method were seventeen months and eighteen months old, respectively. No operative method seemed to be entirely satisfactory. Numerous cases of spontaneous cure, that was disappearance without actual removal of the papillomata had been reported. The case reported was that of a child with a history of increasing hoarseness and difficult breathing during a period of six months before coming under observation. She was evidently suffering from marked laryngeal obstruction. Examination showed a granular mass filling the entrance except for a small chink posteriorly. The child was taken to the hospital and the consent of the parents obtained to do a tracheotomy whenever the writer thought necessary. As breathing was becoming steadily worse a low tracheotomy was done on the following day, a few whiffs of ether being used. At the end of one week the larynx was opened and the masses of papilloma, which practically filled the box of the larynx below the cords and extended above them also, were removed. The patient was discharged at the end of the twenty-fifth day without the tube and with the laryngotomy wound healed. During the following five months she was perfectly well, but six months later she suffered an attack of grippe which seemed to have been the starting point of a recurrence of the papillomata, which necessitated a second tracheotomy, followed a week later by laryngotomy. The following one hundred and fifty-two days were spent in the hospital, the tube being worn continuously so that rest of the larynx would give the greatest chance of allowing the process to run its course without reinfection, if one might use such an expression. The mother became expert in the care of the tube, so the child was allowed to go home, the idea being to allow her to wear the tube for an indefinite period. This proved to be the correct procedure, for three months after discharge from the hospital there were small papillomatous masses on both posterior pillars of the pharynx, which later disappeared spontaneously. The child wore the tube continuously for two and a half years, and was about ready to dispense with it when she died of influenza-pneumonia during an epidemic. The microscopist reported the masses removed as papilloma. The use of the direct laryngoscope, without tracheotomy, in children under four years of age was not justified; in small children tracheotomy followed by opening the larynx was preferable, because this operation when carefully done permitted absolutely perfect access to every portion of the organ and perfect removal without undue traumatism of every particle of the growth. It was not always possible to get a larynx cleared out by the direct method even in adults. The various drugs applied locally in adult cases had in the main been unsuccessful and were not applicable in small children. Radium and *x*-ray exposures had been used and a few good results therefrom had been reported. Cases were reported of cure by removal followed by fulguration repeated at intervals. There were two classes of laryngeal papillomata in children. First, those in which no marked obstruction to breathing existed and in which the patients were in good general condition; and, second, those in which there was progressively difficult respiration. In the first class one might temporize in the hope of a spontaneous cure, supplementing the waiting by hygienic measures. In the second class one must consider (1) removal of the growth by the direct method without preliminary tracheotomy; (2) simple tracheotomy, relying upon laryngeal rest to bring about a cure; (3) tracheotomy followed by direct laryngoscopic removal of the growths, and (4) preliminary tracheotomy followed later by laryngotomy.

Dr. J. PAYSON CLARK of Boston, Mass., adhered to his position previously taken that in these cases no treatment should be undertaken that would cause permanent injury to the larynx or leave a scar. He advocated preliminary tracheotomy in all cases in young children owing to the size of the larynx and the danger of rapid growth and obstruction of the larynx. After doing a tracheotomy the larynx should be given a period of rest. A laryngeal papilloma, like an ordinary dermal wart, would often disappear.

Dr. GEORGE L. RICHARDS of Fall River, Mass., related the history of a case of papilloma of the larynx in a child in which he made applications of alcohol directly to the cord. The papilloma disappeared and during a period of five years, until he lost sight of her, there had been no recurrence.

Dr. CROSBY GREENE of Boston, Mass., described a case of papilloma in a child upon whom he operated once or twice by the direct method. Later he had a recurrence and another surgeon operated by thyrotomy and thoroughly cleaned out the larynx. Within a year he saw the child with his larynx full of papillomata. Such an experience he thought was sufficient reason for not resorting to such a radical procedure as laryngotomy in these cases.

Dr. HENRY L. SWAIN of New Haven, Conn., told of a case of his in which four or five small recurrent papillomata in various parts of the larynx receded under alcohol treatment, during a time when the patient was pregnant and could not be operated upon. Only the original growth remained on the vocal cord. This was removed by direct laryngoscopy, and applications of alcohol to the site from which the growth was removed were employed for some time, with no recurrence.

Dr. ROBERT CLYDE LYNCH of New Orleans, La., said an experience with ninety cases of papilloma of the larynx led him to believe that any cutting operation was likely to be followed by recurrence, and not only that, but it seemed to be followed by a type of papilloma that indurated below the level at which the tumor originally grew. For that reason thyrotomy or any type of operation except that described by Dr. Jackson this morning was not indicated. He had obtained the best results by drying the surface with alcohol and ether, and using either fulguration or the actual cautery. For a time he thought fulguration was the better of the two, but now he was leaning to the actual cautery, applied in the same way as in laryngeal tuberculosis. The performance of tracheotomy early in these cases was to be regarded with fear and trembling because of the danger of scattering the papilloma and implanting it in the trachea. There was a psychological moment for the disappearance of these growths. He had operated upon some cases many times, in one instance forty-two times, and finally a time came when there was no recurrence of the growth.

Dr. D. BRYSON DELAVAN of New York said that in the small, slowly growing and warty papillomata of the larynx the use of alcohol, not once a month (that was too much in the line of prohibition altogether) but every day, by the patient who could be taught to do it, would cure a certain proportion of cases. In another proportion this treatment retarded the growth, and made it easier to remove it and remove it thoroughly. But there were papillomata that such treatment could not possibly cure.

Dr. Oscar A. M. McKimmie of Washington, D. C., said that in so small a child he should probably do again what he did in this case, because he believed that even the method suggested by Dr. Jackson this morning offered as much chance of spreading the papilloma as laryngotomy. The latter in the hands of the average laryngologist he thought was a safer operation.

Presentation of Patients, Instruments, and Reports.—Dr. D. Bryson Delavan of New York presented a patient showing the splendid results following external applications of radium. The patient stated that he had had two hours treatment the first time, and then four and a half hours on each side. They were cross-fired, and the next time he had one hour and fifty minutes on one side. The third time he had two hours. His voice, as they could hear, was coming back. He thought it was better each day.

Dr. Chevalier Jackson of Philadelphia said he felt so enthusiastic over this patient that he would like to say a word. After not so many weeks of perfectly painless treatment, all the enormous masses that had occupied the place of the ventricular bands simply melted away. It approached ideal medicine in a way one practically never saw. It was one of the most brilliant cures he had ever seen. He was so enthusiastic that he had made drawings which he wished to present.

Dr. Jackson then presentd a little girl who had had masses of papillomatous growths removed with the crushing forceps. Her speech was clear and there had been no recurrences.

General Measures in the Treatment of Laryngeal Tuberculosis.—Dr. Lawrason Brown of Saranac Lake, N. Y., presented this communication in which he said that tuberculous laryngitis was rare in children, being more often found at autopsy; it occurred in 25 per cent. or more of adults with pulmonary tuberculosis, slightly more in men than in women, and next to tuberculous enteritis and colitis was the most frequent complication of pulmonary tuberculosis. Laryngeal tuberculosis was rarely, if ever, a primary disease. One vital essential in its treatment was rest. They put the patient on silence and gave the larynx absolute rest except for such movement as occurred in breathing, swallowing, and coughing. The results of this absolute rest were just as striking as they were in tuberculosis of any other organ that could be given nearly 100 per cent. of functional rest. How long absolute rest should continue must depend upon how the lesion progressed. Lip whispering, then ordinary whispering, next an occasional sentence in speaking tones, was the method of progression, but singing, shouting, and public speaking should be avoided for some months after recovery. Personally, Dr. Brown said he went further in the rest treatment and did not hesitate to put the patient to bed for six weeks in a well ventilated room with wide open windows, or better still upon a porch during the day and in a well ventilated room at night. Recovery from laryngeal tuberculosis depended in most instances largely upon the condition of the pulmonary tuberculosis. With advancing pulmonary tuberculosis, fever and poor nutrition, it was difficult to promote healing in a tuberculous larynx, but it had been done with the electrocautery. In regard to local treatment, he felt that the laryngeal dropper, devised by Dr. Yankauer of New York, was not yet widely enough known and used. To produce rest and to facilitate swallowing, freedom from or lessening pain was necessary. Dr. Brown had tried injection of alcohol into the superior laryngeal nerve with some success but the respites had never been long. The insufflation of anesthesine or orthoform had been helpful. In these cases the laryngeal dropper had proved a godsend. Before the application of these drugs he had the patient rinse the larynx thoroughly with physiological salt solution. Menthol (1 per cent.) in oil was an excellent application which to begin the treatment. He had by these methods been able to avoid largely cocaine with its disagreeable after-results. In a few cases he had not hesitated to use morphine hypodermically. More recently he had been interested in a thin solution of gelatin suggested by Mr. Petroff, who had afterward prepared a strongly immune serum (sheep or goat). Spraying the larynx with these substances apparently afforded a few patients marked relief, but in others it was of little avail. In view of the large number of patients with pulmonary tuberculosis who had laryngeal tuberculosis, treatment of the throat condition must in large part devolve upon the medical man doing tuberculosis work. They felt their shortcomings and turned to the laryngologist for help, but when they saw patients with high fever dragged to a laryngological dispensary, which they knew was wrong, they realized that they or some one else had erred.

Climate in the Treatment of Laryngeal Tuberculosis.—Dr. Carroll E. Edson of Denver, Col., read this paper. He stated that tuberculosis of the larynx was practically always secondary to an active pulmonary tuberculosis, and hence the extent and character of the primary lesion usually determined the choice of climate for the patient. It was, therefore, in the first place necessary to have a clear understanding of the part climate played in the cure of tuberculosis of the lungs. This the writer dealt with at length. Tuberculosis of the larynx responded only in a general way and to a slight degree to the increased vitality induced by outdoor life and general nutrition. Its arrest was more dependent upon the third member of the physiologic tried, rest. Under the establishment and maintenance of complete rest the prognosis of laryngeal tuberculosis was much better than commonly believed. Complete rest was incomparably the most important part of the treatment. The most effective means to this end and the most difficult to obtain was silence, the absolute avoidance of all phonation. Next in value was reduction or control of cough from whatever source it arose. Local laryngeal irritation was to a considerable degree affected by atmospheric conditions, the control of which might greatly assuage the patient's discomfort. The supralaryngeal cough caused by nasal and pharyngeal trouble was a factor of great importance in its wear upon the patient. This was not sufficiently appreciated or given enough detailed care, either in laryngeal tuberculosis or purely pulmonary tuberculosis. A patient with laryngeal tuberculosis did not endure well extremes of heat or cold. Climates characterized by sudden or frequent changes of temperature were to be avoided. The patient would benefit most if sent to a mild, equable climate with a dry air, low relative humidity, and long periods without wet weather. Strong winds and dusty air were sedulously to be avoided. Frequently in the same region of generally similar climatic conditions one locality would have a topography giving shelter from the prevailing winds, and would be thus entirely suitable, while a station near at hand not so protected would be undesirable. Such local details were important to consider even after the general problem had been settled. One mistake in the management of these patients was traveling to a physician's office and waiting their turn for treatment in a crowded, often poorly ventilated, room when the exertion involved or the presence of fever should forbid such conduct. A patient with laryngeal tuberculosis needing regular local treatment should be treated at his residence; if this could not be done the patient would be best placed in a sanatorium where the means for local treatment were at hand. A careful consideration of the balance between the patient's needs, his means, and the reasonable advantage to be expected from a change in surroundings was necessary to avoid disappointment or disaster. To make a correct selection the physician must understand the climatic characteristics of both the home and the contemplated resort; he must have an accurate knowledge of and interest in meteorological statistics and be able to interpret them properly in terms of physiological effect on the patient. Future advance in the best utilization of climate would come with a greater appreciation of the fact that the physical modalities of temperature, humidity, sunlight, wind, and barometric pressure were real and definite in their action.

The Treatment of Tuberculous Laryngitis by Suspension Laryngoscopy.—Dr. L. W. Dean of Iowa City, Iowa, presented this paper, in which he asserted that, using proper precautions, endolaryngeal operations might be performed upon the tuberculous larynx by suspension without detriment to a coexisting quiescent pulmonary condition. He found it quite impossible to do as accurate work by direct laryngoscopy as by suspension. Unless there was some contraindi-

cation to its use suspension laryngoscopy was to him the procedure of choice for endolaryngeal operations on the tuberculous larynx. The well illuminated larynx was thoroughly exposed; both hands of the operator were free, so that he might have in one hand a spatula to expose better or to protect a certain area of the larynx, while in the other he held his galvanocautery point, punch, or curette; he was at liberty to turn to his instrument table and select a different instrument without interfering with his work; there was no hurry. The work was done under local anesthesia. There was no excuse for loosening teeth and there should not be the slightest danger of jaw fracture. To get a good view it was not necessary to separate the patient's jaws widely, and it was not always necessary to bring the anterior commissure into view. It was never necessary to raise the patient's head from the table. The anesthesia consisted of morphine $\frac{1}{4}$ of a grain and atropine 1/120 of a grain given twenty minutes preceding the operation. Ten per cent. cocaine was applied to the epiglottis and larynx, using a cotton swab. Suspension prevented hemorrhage and edema by permitting exact incision and cauterization when operating in the larynx and so thoroughly exposed bleeding points that they might be properly handled. For amputating the epiglottis, suspension laryngoscopy was the procedure of choice. Under local anesthesia, using the short Lynch tongue spatula, the epiglottis was distinctly exposed. It was grasped with a tenaculum forceps and, using a Lynch knife, cleanly severed at its base. No hemorrhage of importance followed this procedure. It required but a short time. The decision as to whether the operation was to be performed by direct laryngoscopy or suspension was made by the pulmonary expert. He approved of suspension for those patients who could have the endolaryngeal work done in this way without much risk of a reaction. It was particularly desirable to suspend those patients needing cutting and curetting operations. The first essential in treating laryngeal tuberculosis by suspension laryngoscopy was to have the patient under the supervision of a pulmonary expert who had authority to say that the patient should or should not be suspended. Their tuberculous laryngitis cases were divided into four classes for treatment: (1) those who remained in bed and received only simple medication; (2) those who might sit up and have applied to the larynx mild astringents and antiseptics; (3) those who received rapid endolaryngeal surgical procedures by direct laryngoscopy, and (4) those who were operated upon under suspension. Suspension laryngoscopy was particularly adapted to the treatment of superficial tuberculous ulcerations of the trachea. If these ulcerations were high up, using the laryngeal spatula enabled one to cauterize them readily; if situated low down in the trachea a tracheoscope might be passed under suspension and proper treatment instituted.

Dr. JOSEPH B. GREENE of Asheville, N. C., said it seemed to him that the general man who treated pulmonary tuberculosis was apt to pay too little attention to the laryngeal condition. The treatment of laryngeal tuberculosis depended largely upon the stage of the disease, and likewise upon the site of the lesion. It was obvious that silence, which had been so well emphasized, could have no effect upon lesions of the epiglottis and could influence very slightly if at all chronic infiltrations in other situations of the larynx. In ulcerations of the epiglottis there was no treatment comparable to that of epiglottidectomy. In many cases of ulceration and infiltration he was in the habit of using formalin with a great deal of benefit to the patient. There were certain cases, however, which required the use of the electrocautery. For this treatment he used the indirect method. In conclusion, Dr. Greene emphasized the importance of alcohol injections into the superior laryngeal nerve for pain in laryngeal tuberculosis. The method of making this injection was presented clearly by Dr. Fetterolf in a paper published in the *Annals of Otology, Rhinology, and Laryngology*, March, 1912.

Dr. GEORGE B. WOOD of Philadelphia, Pa., said the only method that in his hands yielded positive results in the treatment of tuberculosis of the larynx was the application of the actual cautery. He did not believe that any drugs checked the progress of the disease except in so far as they prevented secondary infections. However, the application of drugs for the purpose of combatting secondary infection was an important part of the treatment. There was a distinct danger in the use of the punch or other compressing instruments of forcing tubercle bacilli from the local lesion into the neighboring lymphatics, and the cut surface left an open channel for further infection. The value of the cautery was not alone that it destroyed a tuberculous lesion, but in the fact that it revitalized an area which, because of the tubercle, had been deprived of its blood vessels. In a large majority of patients, laryngeal lesions could be cauterized during the ordinary office routine with no more discomfort to the patient than an ordinary laryngeal application.

Dr. ROBERT CLYDE LYNCH of New Orleans, La., mentioned two cases of laryngeal tuberculosis which had yielded very nicely to the sun's rays applied by the patients themselves at a time when the pulmonary lesion was entirely quiet. Suspension certainly facilitated the ease and accuracy of the application of the cautery. He had seen cases of laryngeal tuberculosis treated by Dr. Dean and the healing was beyond expectation. He did not think Dr. Dean said enough about his routine treatment in the institution that he had charge of.

Dr. CORNELIUS G. COAKLEY of New York said he had divided the subject of laryngeal tuberculosis into two parts: (1) The non-ulcerative form, and (2) the ulcerative form. In the non-ulcerative form, most of the patients were able to go away from their homes, and it was perfectly surprising the results that were obtained by absolute silence. In the ulcerative type one did not always get such good results, especially where the epiglottis and adenoid region were involved. The thing which had given the greatest relief from the difficulty and pain of swallowing had been the application of orthoform, 1 grain; and compound stearate of zinc, 1 grain. The patients could be readily taught to make the application themselves by taking the powder-blower and making a pressure of the bulb with inspiration This would carry the mixture over all portions of the lower part of the pharynx, larynx, and even down to the trachea. Dr. Coakley said he had not had a chance to do much treatment with suspension, because most of his patients were able to be put on sanatorium treatment, where he thought they did better than at home. He objected to home treatment because it was difficult to carry out owing to interference from the family.

DR. JAMES E. LOGAN of Kansas City, Mo., stated that he had taken these patients, put them in an old fashioned prairie schooner, and sent them across the plains, instructing them to find the location in which they improved most. Most of them were greatly relieved by the out-door life. To his mind the ideal treatment for patients with tuberculous laryngeal ulceration was to seek the climate that benefited them, and there receive suspension laryngoscopy after the lungs and other conditions had improved sufficiently to accept that treatment. He advised against his patients taking treatment in the altitude in which he lived.

DR. E. ROSS FAULKNER of New York said he had been a patient of Dr. Lawrason Brown for a year and it was largely due to Dr. Brown that he was present today. Dr. Brown had kept him in bed for a year and for three months did not allow him to talk. He had not allowed anyone to touch his larynx by means of suspension laryngoscopy. Regarding rest, a patient might be making progress when his balance might be upset by a very slight thing, which would not affect a normal person. Dr. Ross cited a case in a woman 67 years of age who came to the clinic complaining of hoarseness of four months' duration and that she had lost weight. He operated upon her for what was thought to be an epithelioma of the larynx. It proved to be tuberculous. After closing the wound he left a ridge of tissue which afterwards made a very good vocal cord. The patient had quite a fair voice and the result was excellent. She was very well today.

Dr. EMIL MAYER of New York stated that in his clinic it was customary to give every patient one of the Yankauer droppers, so that he could make these applications. A little strip of adhesive plaster was placed at the distal end so that the patient might

know just how far to introduce it. This invaluable little apparatus was particularly cheap and should be borne in mind. These patients could not be sent away because financially they were not able to go any distance. Dr. Mayer cited a case demonstrating the great value of the galvanocautery.

Dr. Lee Wallace Dean of Iowa City, Ia., in closing the discussion, again emphasized the necessity of placing every case of laryngeal tuberculosis under the care of a tuberculosis expert before a therapeutic procedure was advised. The laryngologist should recommend to this expert what in his judgment would be the proper treatment of the larynx, basing his opinion on his findings. The pulmonary expert should then advise whether the treatment suggested should be carried out.

Mucocele of the Nasal Accessory Sinuses: Two Cases of Pan-Sinus Involvement with Recovery after Interval Operations.—Dr. Virginius Dabney of Washington, D. C., read this paper, in which he presented the various theories as to the etiology of this affection. Injury, congenital showing of the duct, and a high deviation of the septum were given. It was essentially an affection of the young, although the two cases reported occurred in persons 25 and 62 years of age, respectively. While the affection was principally that of the frontal sinus, similar conditions existed in other sinuses. The condition developed slowly without pain but with pressure symptoms. It was not easy to differentiate a mucocele from a malignant tumor, and often an examination of the contents became the only recourse. Empyema was more difficult to differentiate than any other condition. The severity of the symptoms, pus in the nose, and the patient's distress were of help in differential diagnosis. The prognosis of mucocele was uniformly good, and the treatment radical operation with drainage. The cases reported presented the classic symptoms and the extraordinary features that made mucocele of the accessory nasal sinus an interesting study. The nature of the growths, the type of secretion, the long and insidious development, the lack of insistent symptoms, and distention of the cavities were all present with an almost total absence of constitutional signs. In both radical operations effected a cure.

Dr. Otto T. Freer of Chicago, Ill., said that if the uncinate process was the site of an inflammatory swelling, as it often was during antrum, ethmoidal or frontal sinus suppuration, it impinged upon the lower border of the middle turbinate, lying in contact with it so that it completed the floor of the recessus frontalis, making it a partly or completely closed cavity. Secretions were then more or less retained in the recessus according to the amount of uncinate and associated swelling. His experience had not sustained the usual idea that antrum suppuration was secondary to the frontal sinus suppuration in these cases. Chronic antrum suppurations were, in his experience, nearly all of dental origin and the frontal sinus abscess followed that of the antrum. In aggravated cases of this sort the maxillary antrum, the recessus frontalis, and the frontal sinus formed one continuous lake of pus that drained under pressure through small fissures into the nasopharynx. As the fluid escaped with difficulty the result was a mucocele which was most conspicuously evident where it affected the frontal sinus, because the floor of the frontal sinus, which was the roof of the orbit, being a thin place, gave away, and became absorbed with displacement of the eye outward. If the fluid distending the mucocele cavity became sterile it contained merely mucus. He had observed two such cases.

Dr. C. G. Coakley of New York stated that within the past fourteen years he had had two cases that were diagnosed as mucocele. One was a patient in whom eleven or twelve years before, he had performed ethmoid exenteration for orbital cellulitis. He cleaned out the ethmoid only, along the nose, like the second half of a Killian incision. The patient made a good recovery from both the frontal inflammation and the ethmoidal. For a long time one could pass a probe into the frontal sinus and wash it out, until all secretion had ceased. The man disappeared from view, owing to residence in another country. He returned again in June, 1920, with a marked bulging in his forehead and downward and outward displacement of the eye which had been going on for several weeks. The diagnosis of mucocele was made, the frontal sinus opened, and the membrane only partially removed. This gave only temporary relief. In Novemoer he came into Dr. Coakley's hands again, when he completed the operation, cleaning out the right frontal sinus. If one wanted to call these conditions mucoceles, all right; but he thought the pathology was that of chronic inflammation of the mucous membrane, without bacteria being present, or with a low-grade bacterial content, which had become devitalized so that one did not get a growth. Looked at in this way one could better understand what was going on in these cases. The process was that of chronic inflammation, where the outlet had been obstructed with some anatomic disturbance—possibly inflammation and possibly trauma.

Dr. Lewis A. Coffin of New York said that what he understood by mucoceles were cavities confined to the ethmoidal tract which contained oyster-like sterile masses. They might extend into and involve the frontals. The interesting thing was the absolute destruction of all the natural cell walls of the tract and the extension and enlargement of the limiting wall of the cavity. That was the real wonder. He supposed it was due to the action of the osteoblasts and osteoclasts, but how they worked to retain the even thickness of the retaining wall was a mystery. He wondered whether, if, as Dr. Freer had suggested, the condition commenced in the antrum and spread upward, the infection might not come from the teeth. The antrum was so often infected from a diseased tooth that this origin seemed possible.

Dr. Hill Hastings of Los Angeles, Cal., recalled that Dr. Dabney made the statement that the existence of sarcoma with the diagnosis of mucocele was not uncommon. Some years ago he had reported before the American Laryngological, Rhinological and Otological Society three cases of mucocele, in all three of which a diagnosis of sarcoma had been made. In two cases the mucocele had been shown up externally in the orbit; in the third case there was a bulging of the maxillary wall of the sinus with rotation of the teeth. At operation the cyst was found to fill the whole antrum except a small area at the upper and outer angle. He had since doubted his diagnosis of mucocele and was inclined to the belief that it was a dentigerous cyst that almost filled the antrum.

Dr. Joseph H. Bryan of Washington, D. C., said there was a condition known as mucocele, though just what the actual pathology was he was unable to state. Undoubtedly it was an accumulation of pure mucus, due to low grade inflammation that had not gone on to suppuration. It was caused by plugging of a cavity. He believed it was a pathological condition.

Dr. Thomas J. Harris of New York reported a case of pneumocele in a Russian, 33 years of age, who complained of crackling in the frontal region and vague pain over the head. The nose showed distinct ethmoiditis. There was a history of considerable time in the development of the disease. The *x*-ray showed distinct frontal sinus disease. He thought it was a frontal sinus disease plus something else. Radical operation showed a distinct air tumor with a small opening into the frontal sinus, which was filled with pus, and a solitary sinus and an occluded naso-frontal canal. It would seem that the trouble had begun in the nose and proceeded up into the forehead.

Dr. Virginius Dabney of Washington, D. C., in closing the discussion, said Dr. Freer's explanation of the condition as due to the blocking of the natural outlet seemed perfectly reasonable, and was frequently seen. He thought that Dr. Coakley did not mean that there was no such condition as mucocele; he meant that cases were reported as mucoceles which were not of this type. Dr. Coffin spoke of finding very often a bony cyst filled with semisolid matter; this was interesting and fell within the domain of the subject. A cystic turbinate was one stage of a mucocele. Pneumatocele, referred to by Dr. Harris, was spoken of more frequently by the French than by any others. He had not touched upon it owing to its rarity and ease of differentiation, chiefly by crepitation and lack of local and constitutional signs.

(To be continued.)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF MARYLAND.

December 14-17, 1920.

(*Concluded from page* 660.)

OBSTETRICS AND GYNECOLOGY.

1. Differentiate labor pains from other abdominal pains.
2. Explain how the placenta performs its functions.
3. At what stage in labor does concealed hemorrhage occur and give treatment.
4. Explain your method of applying forceps: (*a*) Low L. O. A. position. (*b*) R. O. P. position.
5. Name the different kinds of breech presentations, and which one do you consider the safest for the woman and child?
6. What is meconium and what diagnostic value has it?
7. What is the most frequent variety of extrauterine pregnancy?
8. Name and describe the fontanels that may be felt in a head presentation.
9. What variety of uterine tumor is most frequently seen and how is this affected by the menopause?
10. What infectious disease of the female genitalia may cause extrauterine pregnancy, and how may this be done?

SURGERY.

1. Symptomatology and treatment of acute catarrhal otitis media.
2. Give symptoms, diagnosis and treatment of acute glaucoma.
3. Give the differential diagnosis between a fracture of the surgical neck of humerus and a dislocation of the shoulder joint.
4. Give the diagnostic characteristics of: (*a*) Varicose, (*b*) Tuberculous, (*c*) Luetic ulcer.
5. Name varieties of fistula-in-ano and give treatment for same.
6. How would you treat a gunshot wound of the leg?
7. What surgical conditions occur in the neck? Give symptoms and treatment of the commonest form.
8. Describe rodent ulcers. Give their common locations and treatment.
9. What are the indications for the removal of the mammary gland?
10. Name the causes of intestinal obstruction. What are the signs and symptoms?

ANSWERS.

OBSTETRICS AND GYNECOLOGY.

1. *The characteristics of labor pains*, are.—They occur just before and during labor; they begin in the back, and pass to the lower abdomen, and down the thigh; at first they are feeble, do not last long, occur at long intervals, are not accompanied by contraction of the abdominal muscles, and do not cause opening of the *os uteri*; later on they become more frequent, occur at gradually shortening intervals, are accompanied by contraction of the uterus and of the abdominal muscles, and the os opens more and more; the pains proceed in a kind of cycle—increase, acme, decline, and interval.

2. FUNCTIONS OF THE PLACENTA. "(1) *Respiratory.*—The placenta acts as the lungs of the fetus. The blood leaving the body of the fetus by the umbilical arteries is laden with carbonic acid which it discharges through the placenta in to the maternal blood. From the latter it receives oxygen which it conveys to the fetus through the umbilical vein.

"(2) *Nutritive.*—From the time of the appearance of blood in the chorionic vessels, the fetus obtains its food from the maternal blood by means of the placenta. Nitrogenous substances have been proved to pass through the placenta, although how they do so is not definitely settled. It may be that they pass through as soluble peptones, or it may be that the syncytium acts upon them by some enzyme, and transmits them in a simpler form. Fats also pass through the placenta, and inorganic substances like iron have been shown to be broken into simple compounds by the syncytium and passed into the fetal circulation. The passage of carbohydrates is associated with what is called (3) the *glycogenic function* of the placenta. By this is meant that in the early months of pregnancy before the fetal liver is sufficiently developed to functionate, the placenta takes on its work and stores up glycogen for the fetal body. The glycogen is probably split up into glucose by the syncytium, and as such absorbed. This glycogenic function has been proved in some lower animals, and probably applies to the human placenta also.

"From these statements it will be obvious that the syncytium is not a mere filter, but is probably gifted with considerable activities in the way of selecting and altering the constituents of the maternal blood.

"That it has the power to reject undesirable substances is clear, and constitutes what is known as' (4) the *barrier action* of the placenta.

"It is found, for example, that usually maternal diseases are not communicable to the fetus; that normally there is no passage of the maternal blood cells from the mother into the fetus; that there is no passage of large parasites like that of malaria through the placenta; and that chemicals, except some that are highly diffusible, are not usually transmitted. It is quite true that sometimes the barrier is broken down, and some toxins or organisms, for example, allowed to pass. These cases may, however, quite legitimately be regarded as, in all likelihood, abnormal.

"(5) *Excretory.*—The waste products of fetal metabolism are carried to the placenta and passed through it to the maternal blood. These are not great in quantity, as the active metabolism of the fetus is mostly constructive. It is possible that some urea may be excreted into the liquor amnii by antenatal micturition." (Johnstone's *Textbook of Midwifery*).

3. *Concealed hemorrhage* occurs in the first stage of labor. The treatment is prompt delivery (accouchement forcé), and the woman should be stimulated with strychnine, ergot, and by hypodermoclysis.

4. *Manner of using forceps.*—"They should not be used when the os is undilated, when the head is not engaged, except in placenta prævia, when the membranes are unruptured, when the disproportion between the child's head and the parturient canal is too great, or in impossible positions and presentations. Before applying the instruments they should be sterilized, preferably by boiling; and the patient anesthetized and placed in the lithotomy position. Two fingers of the right hand are introduced into the vagina; the left blade of the forceps is then held almost perpendicularly by the left hand, with the tip of the blade opposite the vulva; the tip is introduced into the vagina, passed along the floor toward the sacrum. The blade is rotated outward in its long axis in order to escape the promontory of the sacrum. The right blade is introduced in a similar manner. To facilitate locking, one of the blades must be rotated forward. If the head occupies the right oblique diameter, as in L. O. A. and R. O. P. positions, the right blade must be rotated; if it occupies the left oblique diameter, the left blade must be rotated. Traction is made in the direction of the pelvic axis until the perineum is well distended. The perineum is then protected by one hand, while the face is swept over it by an upward movement of the forceps. In posterior positions it is necessary to remove the instruments after the head is drawn down to the pelvic floor; after anterior rotation is secured they may be reapplied. If the occiput rotates into the hollow of the sacrum the hands should be depressed as the face is swept out under the symphysis pubis."—(*Pocket Cyclopedia*).

Forceps in occipito-posterior positions: "The blades are put in exactly as for cases where the occiput has rotated anteriorly. But since the occiput is now toward the sacrum, the *extension will, of course, be downward and backward over the perineum*, instead of upward toward the pubes; hence the handles of the instrument, at first lifted somewhat upward toward the pubes to draw the occiput up to the edge of the perineum, must, when the head emerges, be directed *downward and backward*, instead of toward the *mons veneris*. A moment's reflection will show that the short *straight* forceps (without any sacral curves) should be used in these cases; for the said curve is only adapted to follow the axis of the pelvic canal, but during *backward* ex-

tension of the occiput over the perineum the head departs from the axial line and goes in an almost opposite direction. If the *curved* forceps were used, the ends of the blades would impinge against the pubic arch while the handles were being depressed in following the movement of backward extension. Again, owing to the depth of the posterior pelvic wall being three times as great as that of the anterior one, there is so much more difficulty in getting the occipital end of the occipitomental diameter to escape over the edge of the perineum, hence greater danger of laceration, and necessity for extra care that the occipital pole *really* shall have cleared the perineum before extension is attempted."—(King's *Obstetrics.)*

5. *The different kinds of breech presentation* are: Left sacro-anterior; right sacro-anterior; left sacro-posterior; right sacro-posterior.

The left sacro-anterior is probably the safest for woman and child.

6. *Meconium* is the name given to the stools of the fetus or new born infant. Its continuous passage from the vagina of the parturient woman during labor indicates a breech presentation; in other presentations it implies actual or impending death of the fetus.

7. *The most frequent variety of extra-uterine pregnancy* is that which occurs in the Fallopian tube.

8. The *fontanels of the fetal head* are: (1) The anterior, or frontoparietal; (2) the posterior, or occipito-parietal. There are four other fontanels, two on each side, situated at the inferior angles of the parietal bones, but they are unimportant. They are determined before birth by the touch of the examiner's finger against the presenting fetal head.

In L. O. A. positions the small, posterior fontanel is found towards the left acetabulum. In R. O. A. positions the small, posterior fontanel is found towards the right acetabulum. In R. O. P. positions the large, anterior, fontanel is found towards the left acetabulum. In L. O. P. positions the large anterior fontanel is found towards the right acetabulum.

The *anterior fontanelle* is a lozenge-shaped space, formed by lack of ossification in the posterior superior angles of the two halves of the frontal bone and in the anterior superior angles of the parietal bones. It is situated where the coronal suture crosses the sagittal suture.

The *posterior fontanelle* is a triangular depression situated at the point where the sagittal and lamboidal sutures meet; it is much smaller than the anterior fontanelle.

9. Fibroids are the most frequently seen tumors of the uterus. At the menopause, these fibroids *may* atrophy and disappear, or remain stationary, or undergo degenerative changes. The effect of the menopause is uncertain.

10. Gonorrhea is mentioned as a cause of extra-uterine pregnancy; it is said to spread to the Fallopian tubes, causing inflammation and infection there, which result in hardening the tubes, removing their elasticity, producing kinking or stenosis, and so preventing the fertilized ovum from reaching the uterus. It has been asserted that the gonorrheal infection destroys the ciliated epithelium in the tubes; hut this statement has been denied by other competent observers.

SURGERY.

1. *Acute catarrhal otitis media* is frequently caused by acute coryza and the infectious fevers. There is a painless obstructed sensation in one or both ears, impairment of hearing, and tinnitus. The inflammation causes closure of the eustachian tube. Inflation and aspiration of the middle ear and syringing and douching the nares and nasopharynx must be avoided. A moderate spray of Dobell's solution may be used. If pain is present, dry heat, in the form of hot-water bottle, hot stone wrapped in flannel, etc., may be applied. A few drops, warmed, of a carbolic acid solution (1:40), or one of formalin (1:2000), may be instilled into the ear.

2. *Glaucoma* is a diseased condition of the eye, produced by increased intraocular pressure, and resulting in excavation and atrophy of the optic disc, and blindness. It is due to increase of the contents of the eye, hypersecretion, retention, old age, gout, rheumatism, nephritis. *Symptoms:* Visual disturbances, increased ocular tension, hazy and anesthetic cornea, sluggish and dilated pupil, shallow anterior chamber, ciliary neuralgia, cupping of optic disc, blindness. In *acute glaucoma:* "Objective examination reveals marked increase in tension; the cornea is clouded or steamy (due to edema), often presents punctate opacities, and is insensitive (from pressure upon nerve filaments); there is pronounced circum-corneal injection of a dark red color; the episcleral veins are prominent. The pupil is dilated, oval, immobile, and often presents a greenish reflex. The iris is congested, discolored, and dull. The anterior chamber is shallow, the aqueous sometimes turbid. The lens and the periphery of the iris are pushed forward. The lids are swollen and edematous. The ocular conjunctiva is markedly congested and chemotic. No details of the fundus can be seen with the ophthalmoscope, on account of the clouding of the media."—(May). *Treatment:* Myotics, such as eserine or pilocarpine; massage of the eyeball; mydriatics are contraindicated; operative treatment may include paracentesis, iridectomy, or sclerotomy.

3. In *fracture of the surgical neck of the humerus*, the head of the humerus will be found in the glenoid cavity, but it will not rotate with the shaft; the arm will appear shorter; and crepitus and abnormal mobility will be elicited unless there is impaction.

In *dislocation of the shoulder joint*, the glenoid cavity will be empty, and the head of the bone will be found in an abnormal position; the arm will appear longer; there will be no creptus, and no abnormal mobility.

4. "*Varicose ulcer* is associated with varicose veins, and is common in the legs, especially when the small venules in the skin are involved. There is at first congestion, then exudation, and often eczema, and deeply penetrating ulceration. This leads to spread of the inflammatory process in the adjacent veins (phlebitis), and so it progresses. Inflammatory thickening increases the congestion, and cuts off arterial supply, thus adding to the weakening conditions, which are also intensified by any injury to the skin. The ulcer is liable to destroy the wall of a varicose vein and lead to alarming hemorrhage. The skin is dusky, congested, and often discolored by brown stains, which are due to destruction of red blood cells and freeing of their pigment. These ulcers, if neglected, are the most common origin of callous ulcers.

"*Tuberculous ulcer*, usually of the edematous type. It occurs in tuberculosis affecting any surface, and shows a tendency to heal, but to break down again, sometimes healing on one side and spreading on the other. The edges are healthy, or in spreading conditions the skin is often greatly thinned, dusky in color, and deeply undermined. The floor is pale, the granulations are edematous, and there are sometimes sloughs in the middle from poor blood supply. Where there is much discharge, as at the mouth of a sinus, the granulations are very large and flabby.

"*Syphilitic ulcers* occur in secondary syphilis from involvement of the skin in the disease, and more commonly in tertiary, from breaking down of a gumma. When the ulcer is superficial, the edges are 'punched out'; the base is covered with sloughs or scabs, and the surrounding skin is red. In shape it is circular, and, being multiple, the tendency is to coalesce and form irregular patterns (*serpiginous* ulcer), and it tends to heal at one side and spread on the other. When due to breaking down of a gumma the ulcer is deep and of any shape. The base is covered with grayish, broken-down gummatous tissue. The edges are clean-cut or undermined. The surrounding skin is often brown in patches."—(Buchanan's *Surgery.*)

5. FISTULA IN ANO.—*Varieties.* 1. Complete.—Sinus opens into the rectum internally; on to the perineum externally. 2. Incomplete external—A perineal sinus not opening into the rectum. 3. Incomplete internal—A sinus opening into the rectum, but not externally.

Treatment. Preliminary.—Saline aperients for several days. Opium pill, gr. j. twelve hours before. Enema just before operation. *Operation.*—Pass a director up the fistula. Open it completely from end to end. Scrape out all granulations and cut out scar tissue. Cut through all tissue between rectum and the fistula,

including the sphincter ani. Open up all secondary channels and sinnses. Pack deeply with oiled gauze. In cases in which the fistula is superficial to the sphincter, the latter should also be deeply incised as in the case of a fissure. *In chronic or complicated cases.*—Either excise in the lower end of the rectum, retaining the sphincter (Kraske's operation); or perform an inguinal colotomy."—(Grove's *Synopsis of Surgery.*)

6. *Treatment of gunshot wounds.*—"The treatment of wounds due to the leaden bullet is that of any other infected wound in which a foreign body is lodged. Hemorrhage, if present, should be checked at once, and if necessary the patient reacted from shock. For determining the position of the bullet, the *x*-ray is by far the best means. In the absence of the *x*-ray one should ascertain the direction from which the bullet was fired and the position of the body at the time, examine the clothing for the position of perforations in relation to the skin wound as well as to determine whether portions are absent, and see whether or not there is a wound of exit. After disinfection the wound may be explored for the bullet and any foreign body which has been carried in with it. This is best done with the sterilized finger, enlarging the wound if necessary. When deeply lodged out of reach of the finger, a probe may be employed. Various electrical devices have also been invented for the detection of bullets. The bullet may be removed with the finger, or with strong forceps, such as the sequestrum forceps or special forceps. The wound is then disinfected with bichloride of mercury solution and drained with gauze. When a large number of shot are scattered in the tissnes, or when the exact location of a bullet is not known, less risk will often be taken in leaving the bullet than in a long or mutilating operation to remove it."—(Stewart's *Surgery.*)

7. *Surgical conditions occurring in the neck.*—Congenital fistulæ, cervical rib, torticollis, aneurysms, fracture of hyoid bone, cut-throat, foreign bodies in trachea or bronchi, inflammatory conditions, infections with enlargement of cervical lymph glands (from tuberculosis, syphilis, malignant disease, or leukemia), tumors, goiter. A common condition is torticollis.

"*Torticollis*, or wry-neck is a deformity produced by an affection of the sterno-mastoid mainly, and sometimes of the other cervical muscles, in which contraction occurs, which may be constant or spasmodic. The head is drawn down toward the shoulder, and the face is turned toward the sound side. The condition may be acute, permanent, or spasmodic.

"*Acute Torticollis* is due to cold, producing the ordinary stiff neck, or is secondary to inflamed glands lying under the sternomastoid or to caries of the cervical spine.

"*Congenital Torticollis* is present at, or more often appears soon after, birth. In the former case it is caused by developmental arrest, and is accompanied by asymmetry of the face; in the latter case it is due to partial rupture of the sternomastoid during delivery, and snbsequent cicatricial contraction.

"*Treatment.*—The sternomastoid and its sheath must be divided, and an open incision is absolutely necessary to do it safely and effectually. The best point for division is ½ inch above the clavicle. The position of the head should then be rectified and fixed by plaster of Paris over the dressings. In ten days voluntary movements and massages can be begun. In bad cases some apparatus has to be worn for a time, and the best is a band around the forehead, with a rubber cord running down from the mastoid process on the sound side to be attached to the front of a band running round the upper part of the chest.

"*Spasmodic Torticollis* is marked by clonic spasms of the sternomastoid, and sometimes of the other cervical muscles, especially those in the suboccipital triangle. The pathology is unknown, and the prognosis is unfavorable, as extension to other parts follows cure by operation of the first part affected.

"*Treatment.*—Medicinal: Bromides and chloral and the galvanic current are the most likely to be of use. Operative treatment consists of neurectomy of the spinal accessory nerve. If the posterior muscles are affected, resection of the posterior cervical nerves (first, second, and third) must follow."—(*Aids to Surgery.*)

8. *Rodent ulcer* is a carcinoma beginning in sebaceous glands. It generally occurs in patients over forty, and is of very slow growth. It begins as a smooth, rounded knob in the skin abont the nose, eyelids, orbital angles, or cheeks, slowly increasing in size. In time ulceration occurs. The ulcer has a smooth, depressed base covered with ill-formed granulations, and bounded by a slightly raised, indurated, rolled-over edge. There is little discharge if sepsis is prevented, and little or no pain. The lymphatic vessels and glands are not affected, and dissemination does not occur. The ulcer spreads and destroys surrounding structures; even bone is not spared, so that the brain may ultimately be exposed.

Treatment.—Free excision, allowing a margin of half an inch all around. If the situation or extent will not permit this, *x*-ray should be used for ten minutes daily till healing occurs.—(From *Aids to Surgery.*)

9. *Indications for removal of mammary gland.*—Enormous hypertrophy, Paget's disease of the nipple, epithelioma of the nipple, carcinoma, sarcoma, cystic adenoma, diffnse tuberculous or septic disease if breast is riddled with sinuses.

10. *The causes of intestinal obstruction* are: Strangulation through apertures, or by means of bands and contracting adhesions; impaction of foreign bodies or feces; the presence of tumors; volvulus or intussnsception; intestinal paralysis; disease in the intestinal walls ultimately narrowing the lumen.

Symptoms of acute intestinal obstruction.—"Sudden severe pain referred to the nmbilicus comes on, perhaps, after an effort. Shock, evidenced by a weak pulse, a cold, clammy skin, and a subnormal temperature, accompanies the pain. The pain, intermittent at first, becomes continuous. Vomiting is persistent, and soon becomes fecal smelling. The patient becomes exhausted by the vomiting and inability to take food. The abdomen becomes distended, and if the obstruction is not relieved, perforative peritonitis follows, so that the patient dies in about seven to ten days from the onset. Constipation is usually absolute, though the lower bowel may empty itself at first."—(*Aids to Surgery.*)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

TASCHENBUCH DER ÖKOKOMISCHEN U. RATIONELLEN REZEPTUR. By A. FROHLICH and R. WASICKY. 215 pages. Price, 30 Marks. Published by Urban & Schwarzenberg, Berlin and Vienna.

BIDRAG TIL HJERNECHIRURGIENS KLINIK OG RESULTATER. By V. MAGNUS. 138 pages with illnstrations. Published by Merkur Boktrykkeri, Kristiania.

THE PRACTICE OF UROLOGY. By Dr. CHARLES H. CHETWOOD. 830 pages, illustrated. Price, $8.00. Published by William Wood & Company, New York.

INTERNATIONAL HEALTH BOARD. The Rockefeller Foundation, Seventh Annual Report, January 1, 1920, to December 31, 1920. 150 pages with illustrations.

INFLUENZA, AN EPIDEMIOLOGIC STUDY. By WARREN T. VAUGHAN, M.D. 260 pages. Published by *The American Journal of Hygiene*, Baltimore, Md.

BENIGN STUPORS. By AUGUST HOCH, M.D. 284 pages. Price, $2.50. Published by The MacMillan Company, New York.

PARASITOLOGIE HUMAINE. By M. NEVEU-LEMAIRE. 466 pages with 313 illustrations. Price, 24.50 francs. Published by J. Lamarre, Paris.

STUDIES FROM THE ROCKEFELLER INSTITUTE, Reprints Vol. xxxviii. 580 pages with illnstrations and 15 plates. Published by the Rockefeller Institute for Medical Research, New York.

DIE RÖNTGENSTRAHLEN IM KAMPFE GEGEN DIE TUBERKULOSE. By Dr. MANFRED FRAENKEL. 24 pages. Price, 6 Marks. Published by Johann A. Barth, Leipzig.

THAT BOGEY MAN, THE JEW. By G. FRANK LYDSTON, M.D., D.C.L. 136 pages. Price, $1.25. Published by Burton Publishing Company, Kansas City, Mo.

Medical History.

NEW BOOKS AND OLD.

XVI. FARLOW'S HISTORY OF THE BOSTON MEDICAL LIBRARY.

By JOHN RUHRÄH, M.D.,

BALTIMORE, MD.

A FEW years ago Dr. John W. Farlow, librarian of the Boston Medical Library, published a volume which I believe to be unique in American medical literature, that is, a complete history of a medical library. To any one interested in medical libraries this volume will be found to contain many lessons, the chief of which is, perhaps, the fact that if a medical library is to be a success, it must be well housed and have active officers. Growth by leaps and bounds invariably follows when the simple combination just alluded to obtains.

In the early years of the nineteenth century, there sprang up in Boston several so-called "social" libraries, that is, libraries owned in common by proprietors (socii) for their own purposes. The first of this kind was the Social Law Library, started in 1804 and still in existence under its original name, one of the most important law libraries in this country. In July, 1805, the Second Social, or Boston Medical Library was instituted. As was common with early medical libraries in this country, such books as they had were kept at the house of one of the doctors, in this instance at the home of Dr. John Fleet in Milk Street.

From Dr. Fleet's the books were removed to the apothecary shop of the sub-librarian, Amos Smith, at 39 Marlboro (now Washington) Street, and when the Harvard Medical School, in 1810, moved from Cambridge to Boston to some rooms over another apothecary shop, where Dr. J. C. Warren had given courses in anatomy and Dr. Gorham in chemistry, the Medical Library joined forces and made use of one of the rooms for its books. This happened a second time, in 1816, when the Medical School moved into its own new building in Mason Street, the Medical Library again using a room in connection with the very meagre collection of books belonging to the Medical School. Here the Library remained until 1826, when it was decided to turn its books over to the Boston Athenæum. At the time of the transfer there were thirty-one members, and the library was said to contain two thousand books which it had purchased at an expense of forty-five hundred dollars. Strange as it would appear today, the Athenæum appraised these common medical books and paid for them the same amount of money as the Medical Library had originally paid for them. In 1896 these volumes were transferred to the present Boston Medical Library. There is quite a complete series of catalogues of these early books, which are extremely interesting, but space prevents further consideration.

After the original transfer had been made, there remained in Boston three Medical Libraries; one the Boylston Medical Library in Harvard College in Cambridge, established in 1802; the Library of the Massachusetts Medical College, and that of the Massachusetts Medical Society. These were what Farlow calls somnolent collections of books whose use was not encouraged.

The Boston Public Library, founded in 1852, gradually developed the most important medical department in Boston and to it many physicians sent their books instead of to the libraries connected with medical schools or societies, as heretofore. The Massachusetts Medical Society was the possessor of a library of a limited number of books, principally Proceedings and Transactions of Societies, evidently not considered of any great value, judging from the report of Dr. J. C. White, in 1871, in which it was stated that "no one had consulted the books the past year." As a result of this discouraging statement, a committee of two was appointed with full powers to examine the situation and make such disposition of the books as they saw fit. Acting under this authority, they gave the books to the Boston Public Library, where they remained until 1906, when the entire medical section of the Public Library was transferred to the Boston Medical Library, over 11,000 volumes.

In the *Boston Medical and Surgical Journal*, September 14, 1871, the following note appeared: "The members of the Chicago Medical Society are making earnest efforts to found a public medical library. When will our local societies in New England do the same thing. This Journal has an exchange list of more than fifty medical journals on file at the office, which may be consulted by medical men."

Dr. Henry I. Bowditch and Dr. James R. Chadwick took a more active part in the founding of the Boston Medical Library than any one else. Dr. Chadwick's original records tell of the preliminary meetings held in December, 1874, which led to the establishment of the Library in August, 1875, with Dr. Oliver Wendell Holmes as president and Dr. Chadwick as Librarian. Two small rooms at No. 5 Hamilton Place were rented, with Dr. E. H. Brigham in charge as assistant librarian.

The overflowing of these quarters caused Dr. Chadwick, in 1878, to prepare and send out a circular appealing for funds for a new building. He stated that in a little over two years the library had grown to more than 8000 volumes and 5000 pamphlets, making it the sixth largest collection of medical books in this country at that time. In the same year the library of the Surgeon-General's Office in Washington had 40,000 volumes.

The movement to secure larger quarters was successful, and from 1878 to 1901 the library occupied the house No. 19 Bolyston Place, formerly owned and lived in by Dr. Samuel G. Howe and his wife Julia Ward Howe. The new building was dedicated December 3, 1878, the principal speaker being Oliver Wendell Holmes, who gave a remarkable address, learned and witty, which every medical man would do well to read. In connection with the Dedication and continuing for several weeks, there was a loan collection of 72 portraits of deceased Massachusetts physicians, which aroused much interest and resulted in a number of gifts of pictures to the Library.

What was probably the first directory for nurses was started by the Library in 1879, through the efforts of Dr. F. C. Shattuck and Dr. C. P. Putnam. This was prosperous from the first, and at the end of each year, after taking out the necessary running expenses, there was left a substantial sum for

the Library, which was very welcome in the early days when money was a scarce commodity.

By 1881 the library had increased to over 10,000 volumes, 6000 pamphlets and 286 periodicals on file. Three years later there were nearly 15,000 volumes with a corresponding increase in other departments.

After serving for thirteen years as president, Dr. Holmes resigned in 1888, but continued his interest, as is shown by his gift the following year of his splendid collection of nearly one thousand medical books. This added largely to the works on anatomy and to fine editions of the early medical writers.

The library now grew rapidly by gifts from many sources and the building was ridiculously small for the collections which it housed. In 1893 plans were drawn for a new building and a lot of land on St. Botolph Street was purchased, but changing city conditions made the site less desirable during the years that the Library was obliged to wait for building funds. In consequence, the land was sold and a lot on the Fenway was bought, on which the present building was erected. Dr. Farlow goes into considerable detail concerning this matter and it makes instructive reading for those interested in helping their medical libraries.

The new building was completed at a cost of $126,000 and was open for inspection on January 12, 1901, the dedication exercises taking place the same evening. The president, Dr. David W. Cheever, made the opening address and, in concluding, called on Dr. Chadwick, the librarian, in these words: "If any man were named who had collected and created our Library, it is he."

Other speakers were Dr. F. W. Draper, Dr. J. S. Billings and Dr. H. P. Walcott. Dr. Osler made one of his characteristically charming addresses, saying, among other things, "only a maker of books can appreciate the labors of others at their true value."

From the very early days of the Library Dr. Chadwick had been greatly interested in drawing up a proper system of medical classification. He had many conferences with Dr. J. S. Billings at which were discussed the various schemes proposed by different librarians. After much study and thought for years, there was gradually evolved the Boston Medical Library System of Medical Classification, which was published and described in the Bulletin of the Medical Library Association for January, 1918, in an article by Mr. James F. Ballard, Assistant Librarian of the Boston Medical Library since 1909, who with Mrs. E. J. Collins, Cataloguer since 1880, have had a great share in perfecting the present system. With some slight additions, this system was adopted by the Medical Library Association at its meeting in June, 1921, as a standard for medical libraries. This means that the Medical Librarians of the country believe that all medical libraries in the process of formation will do well to adopt it. This is not the place to discuss the subject, but by using more or less uniform classification, the work of librarians will be greatly simplified.

With the new building came a perfect flood of gifts of books and periodicals, which had been waiting for the erection of a suitable building. A most notable bequest was that of Mrs. Sarah E. Potter, in 1904, of $150,000, as a memorial to her late husband, Warren B. Potter. When the new building was planned, it was thought that the shelf space would be ample for years to come, but already it is entirely outgrown. With great foresight, however, the officers of the Library have bought an adjoining lot of land on which they hope to erect a building sufficient for their greatly increasing needs.

In 1917 the Library numbered 93,399 volumes and over 60,000 pamphlets, in addition to a duplicate library of 9,500 volumes. Dr. Farlow has made a chart showing the increase in the number of volumes from 1875 to 1917. The curve rises rapidly, but the sudden and continued increase brought about by the new building is very striking. This is of great importance to the officers of medical libraries, who may here find an argument of value for use when they are urging plans for larger and better quarters for their collections.

The history of every medical library is that just as soon as adequate facilities for proper work are provided, there will be a large increase in the number of volumes received from many, often unexpected, sources. In addition, there must be much expenditure of time on the part of a few earnest workers, who will inspire others with enthusiasm to join in the good work.

Interesting features of Dr. Farlow's book are the thirty-one unusually excellent illustrations, showing the exteriors and interiors of the different homes of the Library, and also photographs of the old catalogues.

Dr. Farlow's book is to be commended to all interested in medical libraries, and as one reads it one feels that its preparation has been a labor of love by the worthy successor of Dr. James Reed Chadwick.

Seventh Centennial Anniversary of the Foundation of the Montpellier School of Medicine.—On August 17, 1220, Cardinal Conrad, legate of Pope Honorius III, gave to this institution its first statutes and conferred on its graduates the right to practise medicine throughout Christendom. The seventh centennial anniversary, however, will not be celebrated until November 5, 1921, this date being chosen because of the session of the Tenth National Congress of Students, which is to be held in Montpellier at that time. The local body of students is organizing for some brilliant festivals, among which will be the inauguration of a monument to Rabelais, Montpellier's most famous medical alumnus, in the Botanical Garden. The date given above—1220—makes the faculty of the medical school the most ancient in the world. The festivities will be attended by the President of France and a great body of scientists. But ancient as is the date, it by no means represents the beginning of medical instruction in Montpellier. As early as in the eleventh century students attended a teaching institution in large numbers, and the beginnings of medical instruction can be traced back even to the tenth century.—*La Presse Médicale.*

Medieval Medicine.—Sigerist delivered an essay on this subject last May (*Schweizerische medizinische Wochenschrift*, August 11, 1921, li, 32) in which he discussed the relative parts played

by tradition and observation of nature. He was unable to find any suggestion of independent thinking up to the time of the Salerno School. The latter was secular and not ecclesiastic and goes back at least to the ninth century. The first great original figurehead was Constantine of Africa, an Arabistic physician, who translated the Arabic masters into elegant Latin. There was no break with tradition at the height of the Salernitan renown; evidences of nature study are not lacking, but the time was not yet ripe for the orderly development of the latter. The more old documents which were translated the greater was the basis of tradition.

The age of the Schoolmen was also at hand with its peculiar viewpoint that all could be settled by dialectic. But during the fifteenth century there was discernible the tendency to individual thinking as a part of the Renaissance. It was inevitable that little could be accomplished in nature study until there had been a universal upheaval. On the other hand, during the centuries which preceded the Renaissance medicine became distinctly practical. Medical schools and hospitals sprang up everywhere. It is singular that the Salernitan School required of its students a five-year course with an extra year of practice, which is the spirit of the present age. Surgery as an eminently practical calling was well developed long before the Renaissance. Dissection was required of the student although the author is not certain that human cadavers were used. The Church took over the entire care of the sick. Without this strong foundation the discoveries of the scientific period must have been greatly delayed and handicapped.

Bourreau, Last Dean of the Old Paris Faculty of Medicine.—This worthy has been deemed eminent enough for a biography at the hands of Dr. Mauclaire. He came of a long line of medical men, was born in 1741, received his degree of Master of Arts at the College of Cardinal Lemoine and in 1760 was inscribed as a medical student. He walked the wards of the Hôtel-Dieu, and during the period 1764-6 defended three theses, the last of which was devoted to the subject of urethral sounds. He began practice in 1766 and we next hear of him during 1771-5 when he was serving as the college librarian and published a two-volume catalogue of its 15,000 books. In 1780 he lectured on surgery in the French language and his efforts were published in a volume which made a hit with the profession. In 1783 he took the course in pharmacy. In 1786 he was made Dean of the Faculty, at an extraordinary time when the claims of the physicians, surgeons, barber surgeons, apothecaries, midwives, and dissenting physicians were all active. He worked for harmony, for freedom of teaching, and the use of the French language for examinations. He had as a watchword "Harmony and Constancy will win." But the times were highly unpropitious by reason of the near approach of the Revolution.

In 1792 all teaching bodies were suppressed. Bourreau was evidently out of favor with the revolutionists for such medical honors as they bestowed did not reach him. When the Academy of Medicine was reorganized in 1820 he was made an honorary member. He had been Dean of the College for 6 years (1786-1792) and during this period edited all the Faculty Transactions. His best-known effort in literature was his textbook on venereal diseases. In private life he was nicknamed "the Benevolent" because of his kindness to poor patients. At the age of 82 he died from a second stroke of apoplexy; after the first attack he learned to read and write again and thus overcame the aphasia. This was the man who has been accused of having wrecked the old faculty, but who in reality did everything possible to stem the inevitable tide.

Alien Physicians in Old Montreal.—The tendency at all periods of history for medical men to seek their fortunes in alien communities is well shown in an account of Montreal practitioners of the XVII and XVIII centuries which is now running serially in the *Union Médicale du Canada*. From the August number we select the following: In the year 1718 one Timothy Sullivan, son of a Cork physician, came to Montreal, and, having changed his name to Timothée Silvain, obtained leave to practise from the Royal Physician, Sarrazin of Quebec. He is listed among the physicians of the Hôtel-Dieu from 1725 to 1730. He married a widow of some prominence, and died in 1749. Hotheaded by nature, he engaged in many quarrels, and was often before the magistrate, where he was uniformly fined as the aggressor. Dr. Spagniolini, who was born in Rome in 1704, came to Montreal in 1732 as a troop surgeon. He practised for many years as both physician and surgeon and died in 1764. He married no less than three times in 12 years.

Dr. Feltz was an Austrian by birth, who practised in Montreal between 1740 and 1760 and perhaps longer. He was for a time surgeon to the Hôtel-Dieu and married twice—the second time a few months after the death of the first wife. He assumed the title of "surgeon-major of hospitals," and illustrated the tendency of successful medical men to invest in real estate, by purchasing a piece of land in the Faubourg St. Laurent and cutting it up into building lots after a period of appreciation in value.

Elixir of Garus.—Not much is known of Garus, whose name has come down to us in connection with this preparation. He is variously said to have been a grocer, pharmacist, and physician and was apparently a Hollander. His elixir is thought to have been a modification of the *elixir proprietatis* of Paracelsus. As preserved in the French Codex it contains aloes, myrrh, saffron, cinnamon, nutmeg, clove, alcohol, sugar, etc. It makes not only a good vehicle for medicines but is also useful as a table liqueur. We know that in 1719 the widow of Garus petitioned to be allowed to sell the elixir. The latter was recommended for a host of ailments—almost as a panacea, in fact—and was accused of having caused a death or two, which was most probably due to the complaint from which the consumer was suffering. The only action was doubtless the purgative property of the aloes, in case enough of it were taken. The widow was kept waiting two years for her privilege but received with it a pension of 2,000 livres. Upon her death the formula passed into the hands of one Benoist.—*La Presse Médicale.*

TRANSFUSION IN INFANTS WITH MALNUTRITION.

THE USE OF THE SUPERIOR LONGITUDINAL SINUS.*

BY SAMUEL B. BURK, M.D., F.A.C.S.,

INSTRUCTOR IN SURGERY, NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL SCHOOL,

AND

LOUIS FISCHER, M.D.,

NEW YORK,

CONSULTING PHYSICIAN, WILLARD PARKER HOSPITAL.

Introduction.—A marked diminution in the quantity and quality of blood in infancy or adult life is benefited by transfusion and its use should become an every-day procedure in hospital and private practice.

In the treatment of blood dyscrasias of primary or secondary etiology occurring in adults, transfusion of blood has been widely accepted. In the treatises of diseases of children, many prominent authors whose books have been published during the past ten years, fail to mention transfusion. Among these are Tully,[1] Ruhräh,[2] Birk and Schlutz,[3] Chapin and Pisek,[4] Sheffield,[5] Goodhart and Still,[6] Niemann,[7] Burnett,[8] Whipman,[9] Garrod, Batten and Thursfield,[10] Hutchinson,[11] and Sutherland.[12]

McKee and Wells[13] mention transfusion of blood in a casual manner in connection with the treatment of splenic anæmia.

Kelly[14] gives it passing mention in the treatment of shock, recommending the use of transfusion with Brewer's paraffined tubes, and also in the treatment of hemophilia.

Kerley[15] notes that transfusion may be useful in the treatment of hemorrhagic diseases of the newborn.

Koplik[16] recommends the use of transfusion in the treatment of melena neonatorum and after hemorrhage in typhoid fever.

Morse[17] in discussing the hemorrhagic diseases of the newborn states that "Transfusion is a serious operation for both parties and should not be undertaken lightly but only as a last resort."

In summarizing "The Remote Demands" in the constitutional treatment of hemorrhage, Campbell and Kerr[18] make the following statement: "And lastly, in rare instances, it may become necessary to consider the advisability of blood transfusion."

Graham[19] pleads for popularizing transfusion when he says that "in the hands of the experienced surgeon, it is not as difficult an operation as many may lead us to suppose and recent improvement in the technique has made it more easy of accomplishment."

Fischer,[20] Griffith,[21] Dunn,[22] and Holt[23] strongly advocate the use of transfusion.

After a careful search we were not able to find the use of transfusion *in malnutrition* recorded in any recent textbook on diseases of children.

Indications for Transfusion in Malnutrition—1. Progressive loss of weight and improper metabolization of food resulting in atrophy with a senile expression.

2. Cold extremities; heart sounds feeble; pulse thready and symptoms pointing towards a general exhaustion.

3. Catarrhal or fermentative colitis with dehydration of the blood, feeble pulse, and signs of imminent collapse.

4. Acute infectious diseases such as typhoid, prolonged scarlet fever, diphtheria, influenza or in postpneumonic conditions wherein a secondary anemia follows.

5. General weakness in premature infants following a prenatal disease as congenital syphilis, or a weakness due to improper food given by a tuberculous mother before the latter comes to the clinician.

6. Weakness due to tropical diseases.

7. The presence of avitaminosis in addition to the use of antiscorbutics.

Maternal feeding affords the best known food. Despite maternal milk many infants are underfed. This deficiency can be supplied by giving complementary feedings of cream and carbohydrate—chiefly maltose. If the infant continues to lose weight and the extremities are cold, then we must direct our attention to the circulatory system. In marasmic infants we have tried hypodermoclysis. The injection of four ounces of warm normal saline solution every 24 hours is oftentimes helpful. Warm saline colonic instillations given at a temperature of 105 to 108 degrees F. will in many instances add fluid to the circulation. Hypodermic medication such as adrenalin or strychnin fails to stimulate the heart action in many instances. In this class of cases the recourse to transfusions may be the only means of saving life. Although there have been excellent results in some cases, we have had failures in other cases.

Historical.—The general use of transfusion as a therapeutic measure has not been readily accepted, nor has it received the attention it deserves. We are fully in accord with the views of Ottenberg and Libman[24] who state that "the tendency is more and more to use transfusion not as a means of last resort but as an ordinary therapeutic measure." Moreover, until recently considerable surgical skill was necessary to carry out this procedure.

Various attempts were made to simplify the technic since the time of its earliest reference in medical literature. A new era presented itself with

*Presented at meeting of the Clinical Society of the Infantorium, New York, N. Y., May 10, 1921.

the development of the Carrel[24] technique of vessel anastomosis as practised by Crile and Dolley,[25] Goodman,[7] and others. More rapid strides in popularizing blood transfusion are due to the use of the paraffined glass tubes of Brewer[27,28] and Fauntleroy[30] and the cannulas of Crile.[26] Various instruments were also devised for joining the vessel of the donor with that of the recipient, notably those of Bernheim,[29] Hartwell,[31] McGrath,[32] Kahn,[33] Elsberg,[34] Frank[34] and Soresi.[35]

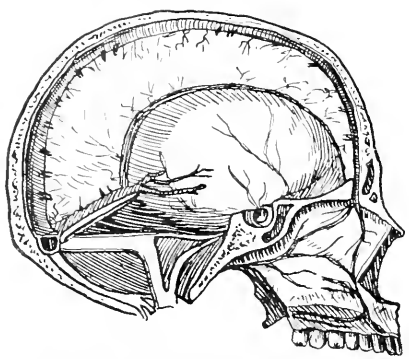

FIG. 1.*—Sagittal section of the skull showing the sinuses of the dura. Note the widening of the superior longitudinal sinus from before-backward. (After Gray.)

The use of the Brown-Kimpton[36] paraffined cylinders and those of Vincent,[37] together with the syringe methods of Lewisohn,[38] Lindemann,[39] Cooley and Vaughan[40] and Abelman,[41] and the apparatus of Miller,[36] Unger[42] and Kush[43] were important progressive steps and increased the value of transfusion. These methods gave an accurate determination of the quantity of blood transfused.

The literature abounds with reports of transfusion since the administration of citrated blood, as advocated in the work of Lewisohn,[37] Weil,[45] Hustin,[46] and Agote.[47]

Hirudin has also been recommended as an anticoagulant by Satterlee and Hooker.[48,49] This agent has been severely condemned because, if used in sufficient quantities to prevent blood clotting, it is so toxic that its applicability for transfusion is out of the question.[7]

Recent reports from the literature indicate an ever increasing number of transfusions in children. Lespinasse[51] reports a blood transfusion in a baby ten hours old, while Woltman[52] records a 60 hour old patient with melena neonatorum who was saved by the injection of 60 c.c. of citrated blood through the median basilic vein. Lewisohn[53] reports a series of seven cases—children ranging from 20 days to seven years—who were benefited by transfusions of citrated blood. He[37] reports an interesting group of cases in infants designated by him as hemophilia neonatorum for want of a better nomenclature. They belong to the same type of cases as reported by Lespinasse. In these excellent results followed the use of citrated blood. Zingher,[54] Lindemann,[55] and Kerley[56] also report favorably on the use of transfusions as a therapeutic agent in diseases of infants and children. Lespinasse[51] reported a series of 14 personal experiences in the treatment of hemorrhagic diseases of the newborn. His results were very encouraging. The patients were referred to him with bleeding from the rectum, stomach, mouth, umbilical cord, and following circumcision. Fischer[57] recommends the use of blood transfusion in the treatment of the severe toxemias of influenza, scarlet fever, and diphtheria. He reports very beneficial results. Moss[58] obtained satisfactory results from the use of transfusion with defibrinated blood.

Sinus Transfusion.—With the use of the indirect methods (syringes, cylinders, apparatus, etc.) great difficulty has been encountered in entering the surface veins in children. There are four places selected for this method: (a) The median cephalic; (b) the median basilic; (c) the external jugular, and (d) the superior longitudinal sinus.

Attempts to enter the veins at the elbow or at the neck are not infrequently attended with great difficulty. Much valuable time may be lost in futile attempts. Exposure by cutting down on the veins subjects a weakened patient to the additional dangers of shock and infection.

In using the superior longitudinal sinus, all objectional factors are eliminated. Up to the age of two years[59] to two-and-one-half,[60] the anterior fontanelle lends itself admirably for this operation.

Tarr[61] was able to puncture the superior longitudinal sinus in a child 3 years old through a cartilaginous anterior fontanelle by using a gold-plated lumbar puncture needle. The same author records a case in which he made 21 entries into the longitudinal sinus during a period of ten days. After the death of this patient, due to a constitutional

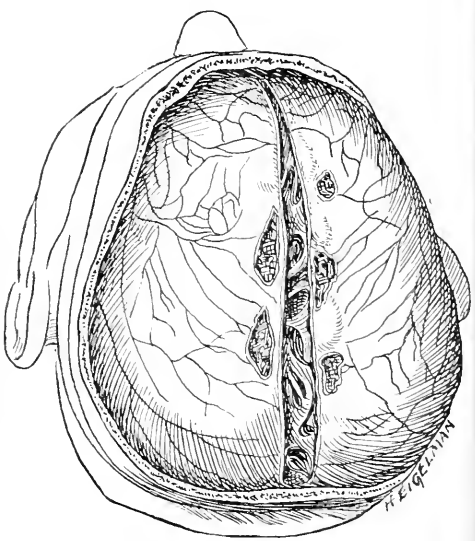

FIG. 2.—Superior longitudinal sinus laid open after removal of the skull cap. Note widening of the sinus in an anteroposterior direction. (Poirier and Charpy after Gray.)

disturbance, autopsy failed to show any visible trauma at the sites of entrance into the sinus.

Fischer,[62] Tarr,[63] Helmholtz,[64] Ratner,[65] Brown and Smith,[66] Goldbloom,[67] Sydenstricker, Mason and Rivers,[68] report the successful use of this route in blood transfusion.

Much of this success is due to the painstaking anatomical studies of Tobler[69] which were inspired by Marfan's[70] use of the sinus for the injection of saline solution. Tobler eliminated all doubts as to the successful use of this method of entering the circulation. In a series of experiments on the cadaver, by the use of colored fluids, he proved conclusively that the sinus could be readily and accurately punctured. In the subsequent study of this subject on the living, he made 50 successful injections of diphtheria antitoxin and gold solutions, the latter for the treatment of lues.

This route has also been used by other observers for the withdrawal of blood for diagnostic purposes (Wollstein and Morgan),[71] and for the treatment of diphtheria (Fischer)[72] and syphilis (Tarr).[73]

Tarr[63] administered dextrose 64 times in 49 infants. He also injected salvarsan and diarsenol in

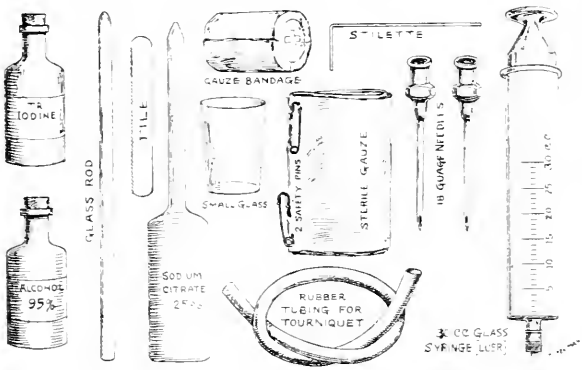

FIG. 3.—Apparatus required for transfusion operation in infants.

8 infants, under two years of age, and in one child less than 28 months old. In 19 patients with so-called acidosis, he had occasion to inject bicarbonate of soda solution and had 15 recoveries.

Fischer[74] has used the superior longitudinal sinus for the abstraction of blood during convulsions in bronchopneumonia and in toxic scarlet fever. He has also administered antitoxin by this route in severe cases of diphtheria and antimeningitis serum for cerebrospinal meningitis.

Many clinicians fear this route for transfusion because of the dangers of injecting fluid into the brain substance. If the usual amount of care is taken, this is avoidable. Several devices have been recommended to overcome this difficulty.

Helmholtz[64] used a combination of the Unger apparatus[42] with a device which steadies the head and supports an ordinary needle introduced obliquely into the superior longitudinal sinus. The objection to this apparatus is that it must be attached to an operating table and is complicated and cumbersome. The needle is introduced through a guide fastened to the child's head by adhesive plaster and set at an angle with the scalp. No provision is made for guarding against penetrating the dura as the needle is fastened in place only after the puncture.

Brown and Smith[66] use an ordinary needle with a short bevel on which is mounted a small amount of solder 2 mm. thick and a quarter of an inch from the tip of a needle. This does not permit any adjustments. Several needles of various lengths have to be kept on hand at all times.

Goldbloom[67] uses a block 3 cm. thick bevelled at an angle of 50 degrees and a needle 4 cm. long with an obturator. A screw is placed through the center of the block to regulate the length of the needle.

Our experience leads us to believe that the more simple the technic, the more readily it is carried out. We make use of the ordinary instruments and containers to be found in a doctor's office.

Apparatus.—One 30 c.c. glass syringe (Record or Luer); several 18 gage 4 cm. needles; 1 ordinary glass jar or drinking glass; 1 glass stirring rod; 1 bandage or rubber tourniquet; 1 tube of sterile 25 per cent. sol. sodium citrate; tr. iodin; 95 per cent. alcohol; sterile gauze.

Donor.—It is well known that the use of indiscriminately selected donors may nullify the value of transfusion or even be disastrous to the recipient. It is therefore necessary to select a vigorous, healthy individual with an approximately normal red blood cell count and hemoglobin content, whose history is negative for lues and whose Wassermann blood test is negative. No one with an elevation of temperature or convalescing from an infectious disease should be used. Moss recommends cardiacs as donors who have a normal blood count and in whom venesection may be indicated.

When the foregoing qualifications have been fulfilled the dangers of incompatibility due to hemolysis and agglutination must be eliminated. Rehling and Weil[75] were among the very early observers in America who laid special stress on the importance of hemolysis tests before transfusion is attempted. Moss[76] showed that the blood group to which an individual belonged could be determined by an agglutination test with his red blood cells and the serums known to belong to Groups II. and III. or with suspension of Groups II. and III. red blood corpuscles and the individual's serum. He found that all individuals fall into four groups as regards the hemolytic and agglutinative qualities of the blood.

..Classification of Agglutination Based on 1,600 Tests (Moss).—Group I. (10 per cent.)—Sera agglutinate no corpuscles. Corpuscles agglutinated by sera of Groups II, III and IV. Group II. (40 per cent.)—Sera agglutinate corpuscles of Groups I and III. Corpuscles agglutinated by corpuscles of Groups III and IV. Group III. (1 per cent.)—Sera agglutinate corpuscles of Groups I and II. Corpuscles agglutinated by sera of Groups II and IV. Group IV. (43 per cent.)—Sera agglutinate corpuscles of Groups I, II and III. Corpuscles agglutinated by no serum.

It is noteworthy that Jansky,[74] working independently, at about the same time, corroborated Moss'

findings. The nomenclature of the grouping is the reverse of that described by Moss. Group I of Moss corresponds to Group IV of Jansky.

The following table shows the relation of the four groups with respect to agglutination (Goodman):

		SERUM.			
		1	2	3	4
Group I	(10 per cent.)	o	+	++	+
Group II	(40 per cent.)	o	o	++	+
Group III	(7 per cent.)	o	+	o	+
Group IV	(43 per cent.)	o	o	o	o

The red cells of Group IV are not agglutinated by any group and therefore it is best to employ only Group IV donors, in which case the recipient's blood does not have to be tested.

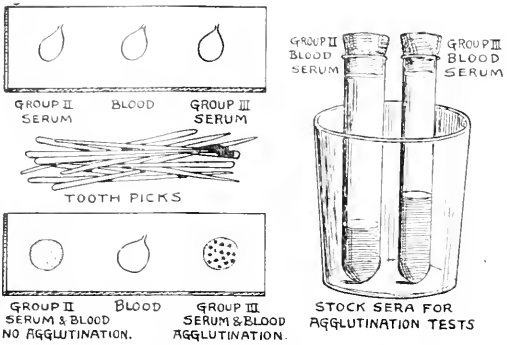

FIG. 4.—Apparatus required for agglutination tests. (See text.)

Moss demonstrated that the absence of agglutination precludes the possibility of hemolysis and described a simple, rapid, and sufficiently accurate method. For our work we followed the technique of Moss as modified by Vincent.[75] The Vincent technique is as follows:

Two prepared sera, a clean glass slide, and a number of clean toothpicks are needed to make the test. One or two drops of Serum II is placed on the left half of the slide, and an equal amount of Serum III on the right half of the slide. The ear or the finger of the person tested is punctured and a small drop of blood is transferred on the point of a knife blade or with a toothpick to each of the sera in turn. The blood is stirred into the serum. The blood should be transferred before the coagulation has commenced and care should be taken to avoid mixing the two sera. Agglutination of the corpuscles is accelerated if the serum is agitated by the slide being tipped from side to side. If the reaction is negative, the corpuscles make a uniform suspension in the serum. If the reaction is positive, the masses of agglutinated corpuscles usually appear in less than a minute and are discernible to the naked eye. Rouleaux formation can be eliminated if the mixture is stirred; agglutination is not broken up in this manner. The reading should be confirmed by microscopic examination.

FIG. 5.—Head being steadied by the assistant with the face upward near the edge of the table.

In order to eliminate contamination in handling the blood and sera a different toothpick or wooden match stick is used in each step of the technique.

After obtaining the proper donor, the front of the elbow region is painted with 3½ per cent. tincture of iodin and a tourniquet applied just below the deltoid region lightly enough to cause the veins to stand out prominently but not so as to obliterate the arterial pulse. The median cephalic or median basilic vein (whichever is more readily accessible) is then punctured, and a predetermined amount of sodium citrate solution is added to make a 0.3 per cent. solution, the assistant constantly stirring the mixture slowly.

Recipient.—The infant is wrapped in a sheet, with the head exposed, and placed flat on the back while the assistant steadies the head with face upward, near the edge of the table. The anterior fontanelle is painted with a 3½ per cent. tincture of iodine and the posterior angle of the fontanelle located with the index finger of the free hand.

FIG. 6.—The anterior fontanelle has been painted with tincture of iodine and the posterior angle located with the tip of the index finger.

Injection of Blood.—The citrated blood is drawn into the syringe with the needle attached. The needle is then slowly introduced into the posterior angle for a distance of one to two cm. parallel to the direction of the inner table of the skull. On entering the sinus, one gets the definite sensation of being within the lumen of a vessel.

This is similar to the experience in piercing the dura in doing a lumbar puncture. The operator steadies the needle with one hand and slowly injects the fluid. There should be no resistance in injecting the fluid if the needle is in the sinus. If resistance is met with, the needle is withdrawn and the procedure is repeated. When in doubt it is always well to withdraw some blood before the injection is begun. The injection of an ounce of fluid should take from 1½ to 2½ minutes. Pressure with a sterile piece of gauze over the site of puncture for a few minutes is all that is necessary for the after-care of the scalp.

Case Records.—In this series of cases the transfusions were performed at the Infantorium in New York City.*

CASE 1. Diagnosis: Malnutrition; Pretubercular Anemia.

Becky W., (smaller and weaker of a premature twin), aged 5 weeks, weighing 6 pounds and 5 ounces. Referred by the New York Hospital Social Service.

Mother died of tuberculosis 11 days after labor.

1st week following admission: Feedings consisted of 5 drams of dryco and three ounces of water, every three hours; patient gained 8 ounces. 2nd week: Gastrointestinal symptoms and cough developed; there was a loss of 3 ounces. 3rd week: Cough, weakness and occasional night sweats; loss of 2 ounces in weight. 4th week: Symptoms persisted; loss of 4 ounces in weight. 5th week: An acute febrile grippe developed and the infant lost 8 ounces; the prognosis at this time was bad.

First Transfusion: Twenty-five c.c. of citrated blood was injected into the circulation through the sinus and 2 c.c. through the jugular vein. During the following two days the food was taken better and there was an increase of 3 ounces in weight. She began to take notice of her surroundings. The stools became normal. During the following 11 days there was a gain of 13 ounces. The weight was now about the same as on admission.

*An institution devoted to the care and feeding of normal and premature infants.

Second Transfusion (two weeks later): Twenty-five c.c. citrated blood injected through the sinus. The face became flushed immediately after the sinus transfusion. The radial pulse was 72. Following the second transfusion there was a definite improvement in the appetite. Patient has steadily gained in weight since the last transfusion. The feedings at present consist of milk, barley water, dextro-maltose and cane sugar. As a diluent, anti-scorbutic, and for the vitamine content, the juice of spinach, carrots, parsnip and celery had been used when prepared by steaming these fresh vegetables in a double boiler. The earthy salts contained in the vegetables have a marked nutritive value as clinically demonstrated by the large number of cases that have improved with this modification of the feedings. No medications had been given this patient.

CASE 4. Diagnosis: Malnutrition; Pylorospasm. Agnes M., aged 17 days, weighing 6 pounds at birth and 5 pounds on admission, was referred by Fordham Hospital. Mother died of tuberculosis when the infant was 11 days old. On admission to the Infantorium infant appeared poorly developed and nourished with a feeble pulse and cold extremities. She was restless, vomited after each feeding, the stools contained curds and mucus, and the buttocks were excoriated. The prognosis was bad. Feedings consisted of 4 drams of dryco and 2 ounces of water every one and one-half hours, of which about one ounce was taken. After the third day, human milk was tried with no better results.

Transfusion: Because of the progressive weakness and loss in weight 30 c.c. of citrated blood were given by way of the sinus, the father acting as the donor. The day following the transfusion, there was a notable improvement in the appearance and appetite of the patient. The feedings which were refused the day prior to the transfusion were readily taken. The stools showed a better digestion of the food. There was less restlessness. The infant gained 6 ounces in one week. During the second week following the transfusion a large quantity of food was taken and well digested. The infant gained 7 ounces during this period. Six weeks later the patient was discharged in a splendid condition.

CASE 6. Diagnosis: Malnutrition; Pylorospasm. John G., aged $5\frac{1}{2}$ months, weighing 7 pounds, was referred by the Brooklyn Department of Charities. Family history has no bearing on the present condition. On admission to the Infantorium the infant appeared prostrated. His skin was dry and his muscles were soft and flabby; the abdomen was prominent and the ribs showed typical beading. There was a thickening of the epiphyses of the long bones. There was sweating of the head and a marked baldness over the occiput. The child was restless, the extremities were cold and he had a poor appetite. The stools were foul smelling and contained undigested food. The infant rarely took more than two ounces at one feeding. Prior to admission a diagnosis of tuberculous meningitis had been made. Examination of the spinal fluid was negative for evidences of tuberculosis or lues.

FIG 7.—The citrated blood is injected slowly.

A Wassermann test of the blood was also negative. A von Pirquet test was negative. In view of the foregoing, a clinical diagnosis of intestinal autointoxication was made. Bulgarian bacilli, buttermilk, and whey with dextro-maltose were included with the feedings. Special care was exercised in connection with the hygiene of the infant and special stress was laid upon the regularity of the feedings. The feedings approximated 65 calories to the kilo. of body weight.

Transfusion. After 2 weeks of careful feedings during which mineral salts were also given, it was noted that no progress was made in improving the condition of this patient and a transfusion was therefore performed. Thirty c.c. of citrated blood were given intravenously through the sinus. This patient had a severe reaction following the transfusion. The radial pulse was small in size, regular in rate and rhythm and 82 to the minute. There was pallor of the face, particularly about the nose and mouth. Lateral and vertical nystagmus and right sided strabismus were observed. On the day following the transfusion the infant showed

improvement. Two days later the appetite improved, the stools became less offensive in odor and a gain of 2 ounces in weight was noted. From this time there was a progressive gain in weight. At present, the infant weighs 17 pounds and is in excellent health.

CASE 12. Diagnosis: Malnutrition; Marasmus. Jane C., aged 1 month, weighing 7 pounds, was referred by the Babies' Welfare Federation. Family history has no bearing on the present condition. On admission to the Infantorium, the infant appeared poorly nourished, was cyanotic and the extremities were cold. Although breast fed, the child did not seem to gain any weight. The stools were green and contained many curds. The weight remained stationary for several weeks.

First Transfusion. Thirty c.c. citrated blood were injected through the sinus. An immediate change in the color of the skin and in the body temperature was noted. The skin, which was cyanotic soon became pink, the cheeks were flushed and the ears assumed a reddish color. The feet felt warmer. The temperature, which had been 97.5°, rose to 98.2° in three hours. On the following day, the appetite improved, the child nursed better, the stools were better in color and the general appearance of the body was improved. On the third day the child showed a gain of two ounces in weight.

Second Transfusion (one week later). After injecting two ounces of citrated blood further improvement was noted. The infant progressively gained in weight, nursed better, slept better, and seemed to have a new lease of life. An apparently lifeless infant was transformed into a very lively one within three weeks after the second transfusion.

4. The time of injection averaged about 90 seconds.

5. Four injections were followed by severe reactions; 7 by moderately severe reactions, and 3 by slight reactions. The severe reactions consisted of a short period of dyspnea which lasted about 25 to 40 seconds. A child who oftentimes cries lustily when the procedure is begun becomes suddenly quiet. Cyanosis of the face and pallor about the mouth appears about this time together with lateral and vertical nystagmus. The radial pulse remains unchanged. The child soon thereafter again becomes noisy and restless. The period of quietude lasts a few minutes.

6. A 0.3 per cent. citrated solution was used in our transfusions without any harmful effects. This amount of sodium citrate facilitated the passage of the mixture through the small caliber of the needle with greater ease than with the 0.2 or 0.25 per cent. solutions.

7. In 4 patients there was a marked improvement following transfusion; in 6 patients there was a slight improvement, and in 2 patients there was no improvement.

8. Feeding should be delayed for at least one hour after transfusion. Children fed before this time

GENERAL SUMMARY
LONGITUDINAL SINUS TRANSFUSIONS

Case No.	Referred by Social Service	Clinical Diagnosis	Date of Birth	Date of Transfusion	C.C. Amount of Blood Transfused	Time of Transfusion	Citrate per 100 c.c. Blood	Reaction Following Transfusion	Subsequent Reaction on General Condition
1	N. Y. Hospital	Pretuberculous Malnutrition Anemia	11-1-20	1-17-21	27	90 sec.	Grains 0.25	Moderate	Excellent
2	N. Y. Hospital	Pretuberculous Malnutrition Anemia	11-1-20	1-30-21	25	90 sec.	0.3	Moderate	Excellent
3	Sloane Maternity	Malnutrition Enterocolitis	11-30-20	2-2-21	30	1 min.	0.3	Slight	Slight Improvement
4	Fordham Hospital	Malnutrition Pylorospasm	1-17-21	2-3-21	28	2 min.	0.3	Slight	Excellent
5	Sloane Maternity	Malnutrition Enterocolitis	11-30-20	2-8-21	30	1 min.	0.3	Slight	Slight Improvement
6	Bklyn. Dept. of Charities	Malnutrition Pylorospasm	8-22-20	2-23-21	30	90 sec.	0.3	Severe	Excellent
7	Dept. of Public Welfare, Bklyn.	Malnutrition Gastro-enteritis	2-1-21	3-27-21	28	2 min.	0.3	Severe	Slight Improvement
8	Babies Welfare Federation	Marasmus Malnutrition	5-1-21	5-10-21	30	1 min.	0.3	Moderate	Slight Improvement
9	Babies Welfare Federation	Atrophy Malnutrition	4-13-21	5-18-21	25	4 min.	0.3	Severe	Slight Improvement
10	Harlem Hospital	Atrophy Malnutrition	4-2-21	5-18-21	30	1 min.	0.3	Severe	No change
11	Kings Co. Hospital	Atrophy Malnutrition	5-7-21	5-26-21	30	70 sec.	0.3	Moderate	Slight Improvement
12	Babies Welfare Federation	Atrophy Malnutrition	5-1-21	5-31-21	30	1 min.	0.3	Moderate	Excellent
13	Babies Welfare Federation	Atrophy Malnutrition	5-1-21	6-7-21	60	1 min.	0.3	Moderate	Excellent
14	Babies Welfare Federation	Malnutrition Enterocolitis	1-29-21	7-15-21	30	90 sec.	0.3	Moderate	None

Summary.—1. Fourteen transfusions were performed on 10 infants.

2. The ages ranged from 9 days to 6 months. Seven were under 2 months of age.

3. The amount of blood injected averaged about 1 ounce.

elapsed vomited.

Conclusions.—1. Transfusion of citrated blood is a simple operation and a recognized valuable therapeutic agent. Its use should become an everyday procedure in hospital and private practice.

2. Transfusion of blood is oftentimes a life-sav-

ing procedure in the treatment of diseases of the hematopoietic system. The so-called hemorrhagic diseases of children are greatly benefited by this operation.

3. Transfusion of blood is valuable in the treatment of malnutrition. It is valuable in treating the cachexias following the acute infectious diseases.

4. Transfusion of blood improves the general condition of patients with gastro-intestinal disturbances who do not improve with formula feedings or with the use of mothers' milk. This is particularly noticeable when marked dehydration is present following failures after the use of hypodermoclysis, rectal instillations and venous infusions.

5. Transfusion improves the prognosis in premature infants.

6. Transfusion of blood is best performed in infants by using the superior longitudinal sinus because of its large caliber and its surficial location.

EMPLOYING ELASTICITY.

A CONTRIBUTION TO THE DYNAMICS OF THE SPLINT.

BY DOUGLAS H. STEWART, M.D., F.A.C.S.,

NEW YORK.

ONE single quality of the ordinary surgical splint that is widely and usually employed is rigidity. An apparent exception might be found in the application of plaster of Paris when, for purposes of moulding, a gypsum-mud is spread upon a dressing. Even in this instance, however, the ultimate desirable aim obtained in the "setting" of that mud is an unpliable stiffness in the resultant splint. As to the metal splint in vogue to-day that of course is rigid, since the only thing elastic and expanding about that is its little overshadowing cloud the "size of a man's hand." A non-union cloud as it were, that must be ignored lest its "shadow fill the whole land." As an index finger to that hand-sized cloud Major Elmslie might be quoted thus: "There appears to be a prevalent belief that in fracture of the humerus counter extension upon the lower fragment is necessary; this is a fallacy; many fractures of the humerus should be treated rather by forcing the fragments together than by applying an extension which tends to separate them."

The present writing deals entirely with the employment of elasticity and should that writing prove not to be pioneer in character, then the author is unaware of that particular shortcoming. All he is sure of is that the article itself never can become popular because it deals solely with materials that are, or should be, at hand; consequently while there is nothing here for anyone to exploit, on the other hand there is much that may interfere with the use of rather expensive, though not necessarily satisfactory, apparatus. Furthermore, it would be little or no trouble to furnish authorities, radiograms, and case reports tending to prove conclusively that in the absence of all support the mere hanging of an arm (for instance) or its swinging at the side like a pendulum is apt to bring about non-union of a fractured humerus, owing to the counter-extension evidenced by the mere weight and pull of that arm itself. In short, the fundamental preliminary to satisfactory union of a fractured bone is that the fragments shall be placed in contact, in good position, and then shall be treated with an elimination of any or all detail that tends to make the chances of good union precarious.

When one has splinted a long bone in the usual manner it often happens that some fragment of the bone ought to be moved into a better position; yet this fragment may neither be shifted nor stirred by any conceivable manipulation of the long flat splint, which may really have been applied in a most careful manner. In the very form, shape, and nature of that splint may be a complete lack of differential or elastic pressure. Therefore what is essential to meet the condition described is some small, additional, auxiliary splint to furnish an elastic force that may be controlled in intensity, may be directed in its exertion, and may be localized in the area upon which it shall be expended. Let us suppose that any long bone (*e. g.* the humerus) after being

splinted in the ordinary way shows this very common image upon its actinogram (Fig. 1).

Perhaps this position may be manually corrected a number of times only to resume its malposition after and beneath an application of the

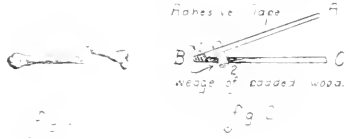

Fig. 2

ordinary splint and bandages. But if one takes a pair of wooden tongue depressors, fastens their left extremities together and thrusts a well-wrapped piece of a third depressor between them, then an engine like the one illustrated in Fig. 2 may be produced.

AB and BC are two wooden tongue depressors fastened securely together with adhesive plaster (1), and separated by a wrapped piece of wood (2). That the ends A and C will tend to spring apart when brought together and in the act will manifest so much or so little resilience as may be desired, needs but trial to obtain a demonstrating conclusion. Let us suppose that a pad be fastened beneath C and that the whole apparatus be applied to a broken bone, such as is shown in Fig. 1, the result might be illustrated as something of the sort shown in Fig. 3.

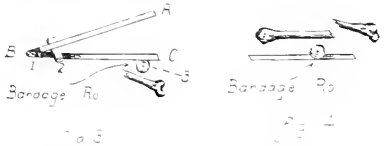

Fig. 3 Fig. 4

In this figure, 3, is a pad attached by adhesive plaster, collodion, or mucilage. Let us suppose again that another depressor be taken, that another pad be attached to its upper surface at the junction of its right and middle thirds (Fig. 4) and that this pad be made to press upon the underside of the bone. Then when all is fastened and bound into place with adhesive plaster strips the result should be about as seen in Fig. 5.

Here A and C would endeavor to spring apart and D and E would tend to reassume the straight line from which they are bent. All of which processes would be attended by motile, non-rigid, resilient or elastic pressures.

The whole could be covered with the usual and fitting padding, together with a compressing roller

Fig. 5 Fig. 6

bandage. After which any ordinary long splint of the rigid variety could be placed on top, or under all, as the case might demand. This simple little mechanism that is here set forth will be found versatile and adaptable in direct proportion to the amount of ingenuity that is displayed by its employer.

The larger sized splints also have elasticity and in making this force available the writer benefits through having two sorts in combination, viz., a rigid one of maple and a flexible one of basswood. But for the sake of simplicity let us here consider the usual thin sort together with everyday roller bandages, wipes, and adhesive plaster. Because if one can use these ordinary means effectively then he can add to those means or can make his utensils as varied or as elaborate as he sees fit, after his experience matures. In any event a good plan is to plot a scheme upon the hospital history chart showing the directions in which the forces are to exert their energies. In this a broad arrow or its conventional representation Λ is a convenient symbol. In Fig. 1, for instance, the preliminary plan would appear thus: $\Lambda \quad V \quad$, so that a very little study would make clear that the broad arrows show the directions in which and the locations on which resiliency is being converted into pressure, after the apparatus is in place, with the plaster strip exercising its restraint and the roller-bandage furnishing the constraint so necessary to a successful issue.

Suppose one wished, for example merely, to exert force according to the following plan:

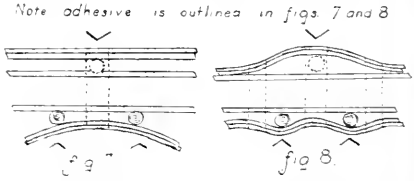

Fig. 7 Fig. 8.

$\Lambda \quad V \quad \Lambda$. Then a firmly rolled bandage must correspond to the broad arrows, in position. Much as though one were to put a triangle of rollers into place. The idea being that, no matter where the broad arrow is on the plan, its place in the bandage must be filled by a roller. (See Fig. 6.)

The elasticity is furnished by thin splints, therefore the outside ones should be doubled, while if the inner ones be left single they will readily adjust themselves to the contour of the limb upon which they are applied. The rolls should be fastened in place by adhesive strips. Then if all were held in proper position and a broad adhesive strip were placed about the center, girth-wise, the desired force would be at once exerted. Because the bent lower double strip would press against the two rollers at its ends while its centers would pull directly down upon the upper roller, as shown in Fig. 7.

Surely it must be quite clear that the bending of the upper double strip into a bow-shape against the roller beneath it, together with traction upon the outer ends of both upper and lower strips, by binding all together, merely increases the force exerted without changing the lines of that force. Because the bow in its endeavor to straighten itself will continue to pull down upon its roller and will pull upward upon the extremities of the lowest double splint.

Whether the elastic splint be employed upon a broken metacarpal bone, or upon the results of an osteotomy that has been performed for a genu valgum, or even upon the non-traumatic spontaneous fractures of tabes, success will depend upon ordinary care in the selection of the right sort and size of material and upon the proper application of that material after selection. The point here emphasized is that the fundamental principles are all the same, the force employed is an elastic pressure; so that mere size or quantity may be varied at will, and may be made to fit any possible set of adverse conditions that may be encountered.

It has been suggested that the value of these observations might be better estimated if it were stated incidentally that they rested upon actual experience in the writer's surgical clinic at the Knickerbocker Hospital (O. P. D.). This clinic is supposedly one of the largest one-man clinics in the world, devoted entirely to acute surgery. At hand are the statistics for last month (June, 1921): Thirteen days' attendance, 510 patients; 15 fractures.

On those fifteen fractures some form of the apparatus above depicted and described was used twenty-two times, if readjustments and replacements are included. This mechanical arrangement for the employment of elasticity has been in use for three years so that omitting all reference to its more or less constant service in dislocations and sprains, to state that it had been applied successfully five hundred times would be but a low estimate indeed and would refer solely to its use in fractures.

128 West Eighty-sixth Street.

ELECTROBIOGRAPHY.*

By ALBERT ABRAMS, A.M., M.D., LL.D.,

San Francisco, Cal.

This term of new coinage suggests the graphic reproduction of organs by aid of the electrical emanations from the latter. The writer has repeatedly demonstrated "the electrical nature of man" by hypersensitive apparatus.

The electrical nature of a nerve impulse has been questioned owing to the fact that its velocity in human sensory nerves is only about 150 feet a second and in motor nerves 190 feet, whereas, electricity travels thousands of miles per second. It is conceded that cold lessens and heat increases the rapidity of a nerve impulse, but no one has seriously considered and this is most important, the nature of the medium conducting an electric current. In gases, electricity is conducted with a velocity approximating 100,000 miles per second, whereas, in liquids the conduction is only about an inch an hour. The ability to conduct electricity varies with the conductor. The relative conducting power of silver is 1,000,000,000 compared with guttapercha 0.000,000,000,004.

When the heart contracts there are electrical variations and when a patient is connected with a sensitive thread galvanometer, the movements of the latter may be recorded photographically. This apparatus is known as electrocardiogram and is the invention of Einthoven. When the writer visited the latter, he found the Leyden (Holland) Physiological Laboratory connected with the hospital by means of telephone wires, so that diagnoses of

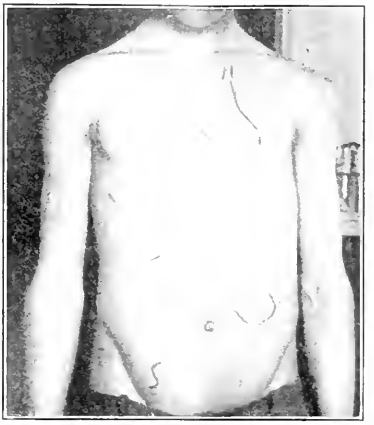

Fig. 1.—Tracing of the heart and blood vessels, lower border of the liver, site of the stomach and appendix (S-shaped).

heart diseases could be made at a distance of a mile without the necessity of seeing the patient.

In 1895, Roentgen, of Würzburg, Germany, discovered, almost accidentally, the *x*-rays which now bear his name. These new rays possessed the extraordinary ability to penetrate many substances quite opaque to light, the degree of penetration being dependent on density. Bone, for instance, is more absorbent than flesh, hence it stands out as dark against the flesh in a shadow cast on a fluorescent screen. At first the application of the

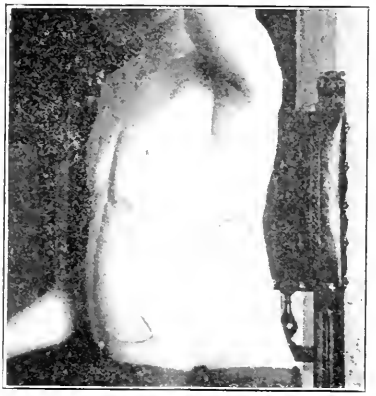

Fig. 2.—Tracing of the spleen. The tracing below on the abdomen is a part of the stomach.

x-ray was limited to medicine and surgery, but its use has been extended to commercial life for the detection of flaws in metals, betrayal of contraband articles, etc. The *x*-rays were of the greatest importance in practical medicine. Estimation super-

*From the "Blanche and Jeanne Abrams Memorial Research Laboratory," San Francisco.

seded "guesstimation" and the organs of the body could be accurately defined.

This is not so, however, with relation to the position of the stomach. The ingestion of a substance opaque to the rays alters the position of this organ and the deduction concerning position and form is necessarily faulty. In the use of these rays, furthermore, we dare not ignore their danger, the expense of the apparatus and the difficulty of transportation, time consumed, etc.

The *British Medical Journal* (Sept. 30, 1916) announced a startling discovery by James Sheaver, relative to the delineation of organs by the electricity generated in the body by aid of elaborate apparatus. Later the same journal repudiated the discovery and since then nothing further has been announced. The present new method suggested by the writer is of the simplest possible character and can be executed by a novice. At the present time of writing the method is necessarily crude, but the use of more sensitive material other than that suggested and further experimentation will elicit better results.

The photographs presented in this article are

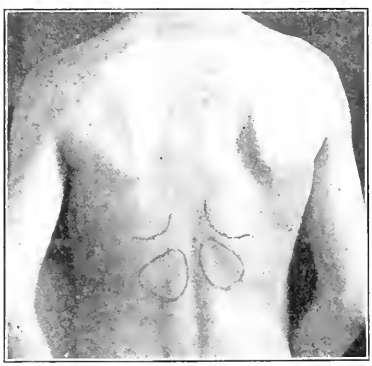

FIG. 3.—Tracing of the lower lung borders and kidneys. The branched tracing in the upper part of the back is presumably the windpipe and its bifurcation.

tracings; but the pith figures could easily be taken directly by an expert photographer.

The tracings (from a 13 year old boy) were made in the presence of the following physicians, who are studying at my laboratory: Mather Thomson, F.R.C.P., Dublin (Ireland) and London (England); Fletcher Sharp, M.D., Canada; W. B. Secrest, M.D., Utah; A. E. Persons, M.D., Buffalo, New York; Z. L. Baldwin, M.D., Michigan; H. W. Danneville, M.D., New Zealand, and Mr. Shipley, a representative of the *Scientific American*. The findings were corroborated by Dr. Mather Thomson, an expert physical diagnostician and consulting physician to the Ministry of Pensions, Great Britain.

Electrostatics.—If a fossil resin (amber) is rubbed, it acquires the property of attracting small bits of paper or wood. This resin was called by the Greeks electron, and later it was called electric by Gilbert, who gave us the word electricity. Practically the whole of electrical science is based on this amber phenomenon of Thales 600 (?) B. C.

It is now known that *any* two different substances rubbed together become electrified.

My investigations show that there is an electric field over every organ of the body and that this generation of electricity is provoked by the incessant activity of the electrons constituting the organ. That the radiant energy evolved is electric is simple of demonstration. In addition, the polarity of this energy may be demonstrated. With a charged pith ball, the borders of the heart and aorta may be accurately defined either by the attraction or repulsion of the pith ball. The left side of the heart is negatively and the right side of the organ is positively charged. When the suspended ball (negatively charged) is held at the proper distance from the heart, it is attracted over the right side and repelled over the left side of the heart. A needle suspended by a silk cord, the point of which is positively magnetized, or another needle negatively magnetized, will act similarly to the pith ball when either is used alone.

Electrobiograms.—By aid of a file, reduce pith to a moderately fine powder (not too fine) and place it in a non-conducting receptacle (glass) with a perforated cover (perforations must be small). Charge the powder by vigorously rubbing a rubber rod with flannel and stirring it in the powder.

The subject is placed in the recumbent posture, with feet to the geographical west (arms and feet separated from his body) on an insulated couch. Rubber under the legs of the couch suffices for the latter purpose. With the skin of the trunk exposed, the charged pith powder is distributed over the organ to be delineated. The skin must be free from fat, and dry to permit the pith powder to move. Distribute the powder evenly and not too thickly. Within one minute the powder shows a clearing around the borders of an organ and when viewed in the proper light this clearing is easily detected.

A fundamental law of electrostatics is that bodies with a like charge repel each other, while bodies with opposite charges attract. It is also a fundamental law in physiology that an active organ is electrically negative to the surrounding parts.

When the negatively charged powder is repelled at the borders of the organs, it is because the latter act like the poles of a magnet and show the greatest activity.

2151 SACRAMENTO STREET.

A PLEA FOR THE RUBBER CATHETER.

BY MAX THOREK, M.D.,

CHICAGO, ILL.

SURGEON-IN-CHIEF, AMERICAN HOSPITAL AND TRAINING SCHOOL FOR NURSES.

IN this article the author wishes to utter a warning against the indiscriminate use of the glass catheter and to urge the employment of an equally convenient and much safer instrument. Our interest in this subject was aroused by a case which came recently under our observation and except for the high degree of honor of the nurse in charge might have resulted disastrously to the patient.

Medical literature is replete with accounts of foreign bodies in the bladder—introduced in many

instances by the patient—but markedly remiss in treating of cases wherein instruments were introduced for therapeutic purposes by the physician or the nurse, and accidentally broken off.

That this occurs all too frequently is our opinion; but either from fear of censure or from failure to recognize the seriousness of the accident no report is made.

The potential danger to both the patient and the physician's ease of mind should indicate the utmost discrimination in the choice of an instrument. The ordinary glass catheter is so generally used in hospital practice because of its convenience and the ease of sterilization that no comment is necessary. Of the several means of sterilization that of boiling is, perhaps, the most frequently resorted to. Glass, unless tempered by special processes for toughening it, is especially liable to fracture under prolonged boiling or when exposed to direct heat. Moreover, the fracture is difficult to detect, especially since the instrument is not permitted to be exposed after sterilization until the instant of its introduction into the urethra. It is not surprising, therefore, that so long as the catheter presents its usual contour, and especially while it is in a moist condition, a quite extensive fracture may pass unnoticed.

The potential danger to the patient from the introduction of a glass catheter which is not perfectly intact, becomes more apparent when we recall that glass fractures in acute angles, leaving points which are quite capable of producing extensive laceration by cutting and even penetrating the tissues with which they come in contact. The sharp cutting edges or sharp points of a broken glass catheter may penetrate the bladder walls and induce peritonitis; or ulceration and perforation into either the peritoneal cavity or the vagina may result.

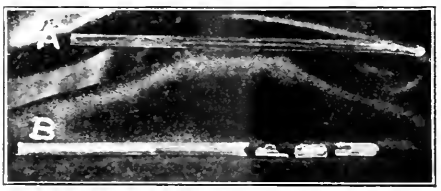
Occasionally a foreign body of this character may remain in the bladder for a long period of time without producing symptoms, but as a rule there are pain, tenesmus, frequent urination, possibly hematuria, and in cases of long standing, involvement of the kidneys, with the consequent renal symptoms. There is nothing pathognomonic to differentiate the condition from calculus and cystitis, hence the diagnosis is usually dependent upon the demonstration of the foreign body within the bladder, unless, as in the author's case, the history is unquestionable.

The treatment is necessarily that of removal, either through the urethra or by cystotomy, supplemented if need be by appropriate medical treatment of the resultant cystitis. If the fragments of glass are small and can be clearly seen through the cystoscope, it is quite feasible to attempt their removal through the uretha, but the operation of choice is generally suprapubic cystotomy.

The only case which we have found recorded which bears a comparatively close resemblance to ours is that of Dr. F. Hawkes, reported in the *American Journal of Obstetrics* in 1914. In this instance the patient had been catheterized; on attempting to withdraw the catheter it broke, leaving a piece in the urethra. The house-surgeon attempted to grasp it, but the remaining portion was broken in two pieces. A No. 12 Kelley speculum was introduced and the fragments removed. There was no hemorrhage or further trouble.

Another case, while not that of a glass catheter, is important in this connection because of the symptomatology. It was reported by Dr. W. C. Danforth in 1918. In this case the patient was a young women seven months pregnant. She was admitted to the hospital on the diagnosis of premature labor. During the preparations for delivery the nurse discovered an object protruding from the urethra. Upon removal it proved to be part of a woven catheter four inches long with a calculus attached, which measured 4 by 1.5 cm. The so-called labor pains ceased and the patient made an uneventful recovery. Cystoscopy at the time and after delivery showed a satisfactory condition of the bladder. The patient had experienced some symptoms of cystitis, but none sufficiently severe to cause her to seek relief. According to the patient's account the only time she had been catheterized was thirteen years before, at which time presumably, the portion of catheter had been left.

Packard, in 1897, reported a study of 222 cases of foreign bodies in the bladder—108 of these were instruments or parts of instruments. That we as surgeons should contribute to this distressing list by the choice of fragile instruments when others



of greater safety and equally satisfactory are at our command, is to be deplored.

We wish to express a positive preference for the use of the rubber catheter on its several merits which may be enumerated thus: (*a*) flexibility, (*b*) greater length, (*c*) choice of caliber, and (*d*) ease of sterilization. Its texture is such that even in unskilled hands no trauma can result. Its length renders the possibility of losing it in the bladder entirely negligible. The different sizes give us a choice which is not possible with the glass catheter, and it can be sterilized with equal facility.

Case Report.—Mrs. T. R., Hospital No. 6899; married; para I; nationality, Italian; admitted May 4, 1921; diagnosis on admission, fibromyoma of the uterus. Family history: negative, other than mother died of pneumonia. Personal history: negative. Menstrual history: 28 day type, three days' duration, until two years ago, when it became irregular. Previous pregnancies: one child five years ago, which died soon after birth from unknown cause. No miscarriages. Previous operations: none.

Chief complaint: during the past five years the patient has had dragging pain in the pelvis and back for two days after the beginning of menstruation, associated with menorrhagia and occasional metrorrhagia. Physical examination: head, neck, chest, and extremities negative. Combined examination reveals a large fibroma of the uterus. Cervix reddened and granular, small amount of mucopurulent discharge coming from the os. Operation, May 6, 1921. Scopo-

lamine-morphine anesthesia; usual preparation for laparotomy. Catheterized prior to leaving for operating room. Catheter glass—usual type—broken during catheterization. Suprapubic cystomy; fragments and broken end of catheter recovered. Closure of bladder. Supravaginal hysterectomy for fibrosis. Closure of abdominal wound; one cigarette drain.

Results: primary union and uneventful recovery.

RADIUM AND RESEARCH—A PROTEST.

By C. EVERETT FIELD, M.D.,

NEW YORK.

DIRECTOR OF THE RADIUM INSTITUTE.

WHEN one has observed and studied the constructive research carried on by the Rockefeller Institute, and has checked up their monthly reports, he feels that truly we have reached a progressive stage of scientific medical investigation. Again a visit to Huntington Cancer Research Hospital at Boston, to witness the intensive efforts there made in the battle against cancer, convinces one that their directors are determined to find some remedy that may materially improve present methods of treatment. The New York State Cancer Research Hospital and the Memorial Hospital of New York are working feverishly to do their part, and their reports are much sought after. Other minor institutions throughout the country are in their way taking up the work with the spirit of confidence and in due season, let us hope it will be soon, a genuine cure for cancer may be found.

During the coming week a well organized educational campaign is being instituted under the direction of the American Cancer Research Society and much good should result. More than 100,000 lives are sacrificed to cancer in the United States each year, and unlike the course of tuberculosis which is showing a declining death rate, cancer mortality is constantly mounting. In 20 years the death rate has increased almost 30 per cent. Surgery, acknowledged by all to be the best weapon at our present command, must be called upon early for favorable result. Radium and the *x*-ray as remedial agents have gained confidence as material adjuncts to surgery. Serums, caustic paste, high frequency, and dietetic measures will be tried according to their special indications. We grant each its place, try hard to use the agent properly, and then often fail to get the satisfactory return.

It is right here that we need the conscientious help of the research worker. The reason for failure with surgery may be known. At certain stages of growth it seems impossible to remove minute islands of cancer cells, invisible to the operator. With radium and the *x*-ray as treatment, the cause of a failure is not so apparent. Radium can destroy a cancer mass, just as surely as does the knife, yet what and why are its limitations? What is its full influence on the tissues, cell structures, and fluids of the body? What is the resistance of adjacent healthy tissue as compared with the malignant structure? What of the metabolic balance that may prohibit further radiation? How can the patient be sustained against the toxic invasion that may be fatal? These are the questions that should be placed before our Research Hospitals. We do not need to be told that radium fails as a cancer cure, but we desire knowledge as to why it fails and to be acquainted with such data as will improve our technic. Those of us who have been working with radium for eight or ten years are enthusiastic in the belief that radiation by radium and the *x*-ray forms today the most important therapeutic measure in advanced cancer work.

The methods of preparation of the element have been greatly improved; the means of application and screenage are rapidly being standardized; the depth of destructive penetration of the rays is being correctly estimated, and consequently during the past two years better clinical results have been attained. That which is now most needed is the aid of real biochemical check-up during the various stages of treatment.

At this time we are constrained to speak in open criticism of a deliberate policy of belittling radium therapy that has been common custom with the Director of the Crocker Cancer Research, Columbia University. During the past eight years periodically there has emanated from this source to the daily press statements that invariably characterize radium as a failure. The same director only four years back, in addressing the graduating class in medicine of Columbia University, stated that "radium was but the weapon of the charlatan and the quack." Such copy found column top space in the daily press from coast to coast and was not responded to by medical men who much dislike debating right or wrong in the papers. This type of publicity in 1916 became so critical as to draw from the pen of Dr. J. Harper Blaisdell, writing to the *Boston Herald* of December 2, 1916, a just rebuke, part of which we quote:

> Briefly stated, your summing up of the findings of the Crocker cancer commission of Columbia University unqualifiedly placed radium in the discard as a "cure," damned it with faint praise as a palliative, and noted with the cheerful abandon of "life" opportunity given the medical profession to make "the patient's condition worse than if he had been left alone." Such is the pessimistic side of the picture based on truth but, unfortunately for your readers, only half the truth. Simply because radium cannot act as a "cure" in inoperable or hopeless cases of systemic cancer is no reason why readers should be instructed to regard it as a discarded fad to the utter disregard of countless cases of early malignant disease that this remedy has saved.

Early in the present month the editor of one of the daily papers requested of us a statement relative to a report as to the merit of radium internally administered for certain types of cardiovascular degenerations. My opinion was desired to offset what was said to be a statement by Dr. F. C. Wood. In this interview (New York *Tribune*, October 14, 1921) Dr. Wood representing the Crocker Cancer Research, is reported to have affirmed that "radium does not increase red blood corpuscles nor prevent hardening of the arteries—it does not have a stimulating effect on the appetite—if anything it kills the red blood cells. All these qualities have been proven in experiments made on human beings. As for *radium in cancer work*, it effects very few cures, *perhaps one out of every thousand.*"

The author since 1913 has made over 7000 intravenous injections of radium element, in dosage of from 10 to 100 micrograms and has invariably witnessed remarkable increase in the red cell

count—with only one exception to the contrary. Furthermore, radium markedly increases appetite and all digestive functions. In early cardiovascular degenerations it has been favorably reported for twelve years back. Probably three score of careful radium therapists here and abroad will bear witness to such facts. As for the statement that perhaps radium would cure one case in a thousand of cancer, we might justly query "How comes even the one case?" What does it all mean? We confess we are entirely in the dark as to the purpose of any policy that permits such statements to emanate from a research institution.

If Dr. Wood is right and radium is to be classed as a failure let us have the truth with reasoning. England today has eleven radium hospitals municipally owned; Japan is doing remarkable work at the Imperial Institute with three grams of radium; France and Germany have notable equipments; even India has recently received her first radium and the Philippine Islands have $90,000 worth of government owned radium. Six South American republics have secured radium equipment. New York State recently purchased $250,000 worth of the rare element and needs more. Bellevue Hospital has voted its urgent needs. Millions of capital is tied up in the four great radium producing companies of America, and they are all trying to increase their output to meet the demand. If it be true that radium is of so little value we might well ask these people to junk their mines and devote their money to a better use. Who of us would have the heart to hold out to the cancer victim a hollow mockery that radium would "perhaps cure one case in a thousand." No! such is not the case. Radium has a mission for the support, relief, and possible cure of the cancer case that makes all the danger of its manipulation and study worth while. Even in the hopeless and inoperable case, it is the one remedy, together with the *x*-ray, that will bring a measure of relief and comfort that nobody would withhold. We will repeat a favorite personal quotation, "Radium is today the most remarkable therapeutic agent emanating from the laboratory of the Almighty."

205 West Seventieth Street.

DIATHERMY IN THE TREATMENT OF TUBERCULOUS KIDNEYS

By CHESTER TILTON STONE, M.D.,

BROOKLYN, N. Y.

In October, 1918, a male Italian, age 37, was referred to me. He complained of pain in the left side which was referred to the tip of the ensiform and to the penis. He also complained of burning urination with marked bleeding and passage of clots at times. During his 18 years of married life he had become the father of ten children. For over a year he had been unable to do any work. His family history was negative. Up until this present attack, which started with pains and frequency, he had been well. Venereal history was negative. Physical examination showed fine râles at the left apex, no loss of weight, abdominal tenderness to deep pressure, both front and back, over the region of the left kidney; no vomiting. The urine microscopically was cloudy and milky, giving in a 6 oz. sedimentation glass 4 oz. of pus. There was 10 per cent. albumin, strong indican, urea 9.6 per cent., sugar negative. Bacteriologically, numerous tubercle bacilli were found. His prostate was tender and boggy and his seminal vesicles distended.

Cystoscopy showed a congested urethra, bladder normal capacity with walls congested and marked hyperemia of the mucous membrane. The trigone was covered with bullous edema. There was no residual urine and no evidence of a growth. The prostate was enlarged and congested. The ureteral orifices were obscure. On being found the left one was seen pouting. The sphincter was hyperemic. The verumontanum was large and congested. On catheterization the left kidney gave 20 per cent. albumin; the urine was loaded with pus and tubercle bacilli; the right gave 10 per cent. albumin, but no tubercle bacilli were found. The functional tests showed the right functioning well, with practically little functioning in the left.

I placed him in the hospital for a week's observation. At the end of this time he was prepared for operation, my intention being to remove his left kidney. To make more sure of my ground, however, I again cystoscoped him, finding tubercle bacilli present in both kidneys. Upon being informed that an operation was unwise, both he and his family pleaded that I use some method to try to restore his health and spare him for the family, as he was their sole support.

At that time I had been reading some interesting articles by Philip Geyser on diathermy and as a result had been doing some experimental work on the kidneys along that line. Among other experiments was the impregnation of meat with live tubercle bacilli cultures and determining the strength, dosage, and size of electrodes necessary to kill the bacteria with the least damage to the meat.

I, therefore, resolved to put the test to practical proof. At the beginning of our experiment his weight was 137 pounds, and he was so weak that he had to be carried into the office. This was in May, 1919, the interval being used to try to build him up and to prepare him for the treatment. The initial treatments were at weekly intervals. The D'Arsonval current was employed with a four-inch lead electrode anteriorly and a six-inch lead electrode posteriorly. These were so placed that the hot point or center of the rays focused in the left kidney. The initial dosage was 500 ma. for a period of one-half hour. This was later increased to 1000 ma. for 10 minutes. The treatments were continued over both the left and right kidneys to December, 1919. At this time no tubercle bacilli could be found in his urine, no microscopic pus could be found, and but a faint trace of albumin showed. He then returned to work. During 1920 he took six treatments for a slight attack of pain. On January 29, 1921, I again examined him. His weight was 157 pounds. He was working every day and was free from pain. The urine was negative, cystoscopic examination was negative.

We may not say that this is an absolute cure; only time will tell us that. He is, however, relieved of all the symptoms of which he complained and is again able to work and support his family.

62 Pierrepont Street.

THE MEDICAL ASPECTS OF WORKMEN'S COMPENSATION.

By THE PUBLIC HEALTH COMMITTEE
OF THE NEW YORK ACADEMY OF MEDICINE.*

I. The Problem.—Recognition by society of its obligation to the worker in certain hazardous occupations has taken form in workmen's compensation laws. New York State passed such a law in 1913, which, according to competent opinion, stands favorable comparison with that of any other state in the Union or any foreign country for the liberality of its provisions.

The New York Compensation Law covers nearly 80 per cent. of all the wage earners in the State. A conservative estimate places the number of industrial accidents in this State at 350,000 a year, or approximately 1000 a day, of which 60 per cent. occur in New York City. Of these about 18 per cent. are compensable, that is, cause disability of more than two weeks' duration, and about 2000 result in death. The amount paid out each year for compensation is estimated at twenty million dollars.

For some time the feeling has been growing that society has not discharged its debt to the injured workman when it pays "compensation" and leaves him, maimed or ill or mentally unfit, to fend for himself with his additional handicap. He becomes a liability to the community in proportion to his incapacity for productive labor and it is, therefore, to the interest of the community to restore him as completely as possible to his normal condition of living.

The success of this idea with war cripples has undoubtedly given stimulus to such work among industrial groups. Not only have great strides been made in traumatic surgery, but the study and treatment of the neurotic conditions known as "shell shock" have shown the possibilities for preventing and curing similar industrial neuroses. It has been estimated that about 10 per cent. of all compensable cases are cases of such neuroses. Prompt recognition and immediate treatment are essential to arrest the development of this condition.

The war has also shown the possibilities of vocational reeducation and the value of occupational therapy for men still in hospitals.

II. The Provisions of the New York Law.—A brief summary of the Workmen's Compensation Act of New York State will indicate the extent to which New York is endeavoring to meet the problem. Employers of labor in hazardous occupations—and this affects the 80 per cent. of all wage earners mentioned above—are made directly responsible for the payment of certain fixed compensation for accidents and for supplying needed medical attention for sixty days. The scope of this law has recently been extended to cover so-called "occupational diseases," arising directly out of the conditions of labor, but not due to a specific injury. The burden of this compensation is through the industry ultimately shifted on the consuming public.

To safeguard the employee, should his employer go into bankruptcy, the employer is required to insure himself either in a stock or mutual insurance company, or in the State Fund; or he must furnish evidence that he will be able to pay any compensation claims made against him. Employers so bonded are termed "self-insured."

The law allows compensation in accident cases as follows: for the "waiting period" of fourteen days, no compensation (unless the disability lasts more than seven weeks); for each week of disability thereafter, two-thirds of the weekly wage, not to exceed $20 nor to be less than $8. In case the weekly wage is less than $8, the whole amount is paid. As 70 per cent. of industrial accident cases recover in the first week and 12 per cent. in the second, these compensation provisions affect only 18 per cent. of all injured workers.

For the loss of a member compensation estimated at the rate of $20 a week for a specified number of weeks is paid. Examples of these specific awards are shown in the tables given below. These sums are paid in weekly installments, the intent of the law being to pay compensation in lieu of wages. For facial disfigurement and head and back injuries a lump sum is paid in settlement.

Comparison of some of these awards with the schedule formulated in 1917 by the Committee on Statistics of the International Association of Industrial Accident Boards and Commissions is shown in the following tables. The schedule of the committee, while not intended as an ideal basis for compensation awards, but as an attempt to obtain a more accurate measure of industrial hazards, furnishes a certain standard of comparison. It will be seen that the New York State law, liberal as it is when measured by other existing laws, must be made still more liberal in order to furnish really adequate compensation for injuries.

	Standards of International Committee	Provisions of the New York State Law	Percentage of adequacy of New York's schedule
Permanent total disability..	1,000 wks	Life	100%
Loss of arm (at shoulder)...	750 wks	312 wks	42%
Loss of hand.....	500 wks	244 wks	49%
Loss of thumb.....	100 wks	60 wks	60%
Loss of index finger.....	50 wks	46 wks	92%
Loss of leg (at hip).....	750 wks	288 wks	38%
Loss of foot	400 wks	205 wks	51%
Loss of great toe.....	50 wks	38 wks	76%
Loss of sight of one eye....	300 wks	128 wks	43%

If the International Committee's schedule is taken as 100 per cent. adequate, the New York schedule appears low. Omitting the figures for permanent total disability, the adequacy of the New York schedule for an average of all the injuries given is 56 per cent. of that of the committee; for an average of the major injuries (*i.e.* loss of arm and leg)

*This study was made by Dr. Ransom S. Hooker and approved by the Committee. The membership of the committee is as follows: John S. Billings, M.D., Nathan E. Brill, M.D., Samuel A. Brown, M.D., Robert J. Carlisle, M.D., James B. Clemens, M.D., Rufus I. Cole, M.D., Charles Loomis Dana, M.D., Arthur B. Duel, M.D., Haven Emerson, M.D., Lewis Fox Frissell, M.D., Arpad G. Gerster, M.D., S. S. Goldwater, M.D., John A. Hartwell, M.D., Ward A. Holden, M.D., L. Emmett Holt, M.D., Walter B. James, M.D., James Alex. Miller, M.D., Charles E. Nammack, M.D., Walter L. Niles, M.D., Bernard Sachs, M.D., Thomas W. Salmon, M.D., Charles Hendee Smith, M.D., Frederic E. Sondern, M.D., M. Allen Starr, M.D., Howard C. Taylor, M.D., W. Gilman Thompson, M.D., Philip Van Ingen, M.D., Karl M. Vogel, M.D., George B. Wallace, M.D., Cassius H. Watson, M.D., Herbert B. Wilcox, M.D., Linsly R. Williams, M.D., E. H. Lewinski-Corwin, Ph.D., Executive Committee.

it is 40 per cent.; and for an average of the minor injuries it is 62 per cent. This schedule refers only to time. The percentage of adequacy is reduced by the provision in the New York law, allowing only two-thirds of the wages. The following table illustrates a comparison in money benefits for a man earning $20 a week:

	International Committee	New York State	Percentage of adequacy of New York's schedule
Permanent total disability..	$20,000	$13,333a.	67%
Loss of arm (at shoulder)...	15,000	4,160	28%
Loss of hand.....	10,000	3,253	33%
Loss of thumb.....	2,000	800	40%
Loss of index finger.....	1,000	613	61%
Loss of leg (at hip).....	15,000	3,840	26%
Loss of foot.....	8,000	2,733	34%
Loss of toe.....	1,000	507	51%
Loss of sight of one eye....	6,000	1,707	28%

a. New York gives a life benefit, but this sum is calculated on the 1,000 weeks provided in the Committee's schedules.

Again omitting the figures on permanent total disability, the adequacy of the New York schedule for an average of all the injuries given is 38 per cent.; for an average of the major injuries it is 27 per cent., and for an average of the minor injuries it is 41 per cent. Below is a table of these average percentages.

	All Injuries	Major Injuries	Minor Injuries
New York time benefits....	56	40	62
New York money benefits..	38	27	41

It will be seen from the foregoing table that the relative adequacy of compensation in time and money benefits is much less for major injuries than for minor injuries, in spite of the fact that the major injuries have a much more deleterious effect on earning capacity than have the minor injuries, and, therefore, a more lasting effect on industry.

At present the law does not allow compensation for the period of disability concurrently with the granting of specific awards. That is, if a man receives compensation for sixty weeks for disability as a result of complications arising from the loss of a thumb, his claim for the specific award of sixty weeks' disability—the award allotted to such injury—is disallowed on the ground that he has already been paid sixty weeks' compensation. An amendment to the law has been suggested, making it possible to grant both awards for the same injury.

In case of death compensation is paid to survivors of the workman on a weekly basis, the amount varying according to the number of dependents, but the total must not be more than two-thirds of the weekly wage nor exceed $20 a week. Widows or widowers receive compensation for life unless they remarry, children until they are eighteen years of age. The average death case costs the insurance company about $4000.

If the worker dies without dependents, $1000 is appropriated by the insurance carrier and paid into two state funds, $100 to a special fund to pay compensation in case of the loss of a second member, and $900 to the vocational re-education fund. The first fund referred to is used in the case of a one-armed man, for example, who loses a second arm. The employer pays compensation for the loss of the second arm only, the additional compensation to the worker being paid out of this special fund.

III. The Administrative Machinery.—Under the reorganization of the State Department of Labor this year, the administration of workmen's compensation laws rests with the State Industrial Commissioner, appointed by the Governor for a term of four years. The judicial duties connected with workmen's compensation are performed by an Industrial Board of three members, also chosen by the Governor. This Board determines all claims for compensation, all claims for medical service or attorney's fees and enforces the provision of proper medical attention for injured workers. A number of referees are appointed by the Commissioner, whose duty it is to conduct hearings and to determine claims for compensation. Their decisions in compensation cases stand as the decisions of the Industrial Board, unless altered by the Board itself.

A compensation case is considered closed when the final award is made or compensation disallowed, but as a matter of fact it may be reopened at any time on application of the claimant, the insurance company or the Industrial Board, the Chairman of the Board deciding whether or not a new hearing may be granted. Cases may be appealed, within a limited time, to the Appellate Division of the State Supreme Court on a question of law only. The finding of the Industrial Board on a question of fact is final.

According to the Workmen's Compensation Act, the employer is required to provide a maximum of sixty days' treatment for any industrial injury, but the Industrial Board may, where the nature of the injury or the process of recovery indicates a longer period of treatment, require the same from the employer. This provision, by a liberal interpretation of the law, affords practically unlimited treatment.

If an employer fails to provide a physician, or if the employer's physician is rendering inadequate or improper treatment, the employee has the right to select his own physician at the employer's expense.

Before a final award is made, the claimant is sent to a physician for an examination and report as to the extent of his injury and the necessity for further medical treatment. In some of the upstate districts this examination is made by a member of the Medical Department of the Compensation Bureau; in other districts to which no member of this Department has been assigned, a physician is selected by the Referee holding the hearing and is present to examine the claimant at the hearing; he is paid by the insurance company involved. In New York City there is a staff of full-time physicians belonging to the Medical Department of the Compensation Bureau who make the examination. The physician of the claimant and the physician of the insurance company may be present at these examinations. The duties of the medical staff of the Compensation Bureau include the physical examination of claimants, the review of medical testimony at hearings, the examination and medical analysis of claim papers, the giving of testimony and cross-examination of witnesses at hearings, and the recommendation of specialists at the request

of the Commission. They make something over 20,000 physical examinations a year. Considering the importance of the work done they are absurdly underpaid, as are all doctors connected with the Bureau, especially as they give their full time service. The salaries paid are as follows: The Chief Medical Examiner, $6,000; one assistant medical examiner, $3,250; three assistants, $2,500 each and one assistant, $2,250. The Medical Advisor of the State Insurance Fund receives $3,500 and three medical inspectors of factories $2,500 each.

It is sometimes difficult to decide whether a disability is the result of the injury as claimed, or whether the condition existed prior to the accident. In such cases, the workman is sent to a specialist for examination. For example, a man may receive an injury to an eye and sustain thereafter partial loss of vision. His natural conclusion is that the injury caused the blindness, but it may be that the loss of vision is due to a cataract which existed before the injury. In cases where the cause of disability cannot be determined by the specialist, the presumption is always in favor of the employee. Charges of the specialist for such examination are forwarded through the Medical Department of the Compensation Bureau to the insurance companies and payment returned by the same route.

In Ohio much "red tape" is eliminated by having the attending physician file a report of his estimate of disability. If this report is in accordance with usual findings in such cases the estimate is accepted without further examination. It is only in unusual cases that a special investigation is made by a medical claim examiner acting under the Industrial Commission. In unusual cases, the local medical examiner makes a prompt examination, so that his report reaches the Commission before the first compensation payment is due. The "waiting period" is only one week, after which compensation is allowed. If the examiner's report differs from that of the attending surgeon, the decision is left to a specialist agreed upon by both, and the Commission pays for the examination. By reason of this direct settlement of medical questions, less than 1 per cent of all compensation claims come up for hearings before the Commission.

The State of Washington provides for local medical aid boards, each board to consist of a representative of employers and employees to administer the medical service under workmen's compensation. These boards must provide care for the injured and are responsible for reporting data concerning all accidents to the State Medical Aid Board, and for certifying physicians' bills.

The Workmen's Compensation Bureau, one of the largest bureaus of the New York Department of Labor, is financed, nominally, by an appropriation from the State Treasury. As a matter of fact, all expenses of this Bureau are refunded to the State Treasury. Each year the State Insurance Fund, the insurance companies and the self-insurers submit a statement of awards, excluding medical service, paid by them during the year, and a pro rata percentage of these awards is assessed on each, to cover the expenses of the Compensation Bureau. The cost of the operation of this Bureau is a very small item in the running expenses of insurance companies, being only about one-half of one per cent. of the value of premiums paid.

IV. The Choice of Physician.—All injuries, no matter how slight, are required to be reported by the workman, and the employer must in every case, whether or not the injury is compensable, furnish medical attention. This requirement gives rise to much controversy concerning the rights of employer and employee to select the physician. The employer holds that since he must pay the bills he has a right to select the physician or surgeon employed. The principal arguments in favor of this plan are, briefly:

1. That it is to the interest of the employer to return the worker to industry as quickly as possible, and he will, therefore, endeavor to provide the best medical aid obtainable to insure the speediest and most complete recovery;

2. That his judgment is better in selecting the surgeon for any given type of injury than that of the workman who may be illiterate, ignorant of hygienic principles, and often not even able to speak English;

3. That many accident cases must be sent to hospitals having their own staff of doctors for treatment of various types of cases. If the patient were to insist upon calling in his own physician, much confusion would result and the patient, furthermore, would often suffer the disadvantage of being treated by a man not experienced in the treatment of his particular injury. It is not yet generally recognized that traumatic surgery is a specialty requiring special training, after a solid foundation in general surgery;

4. That the employer's physician would do his utmost to prevent malingering or simulated traumatic neurosis. He should, if properly selected, be sufficiently skilled in the treatment of accident cases to prevent to a very large extent the creation of a real neurotic condition arising from the shock of the injury and the workman's worry about himself and his family, and

5. That the employment of a plant physician, as is the practice in many large establishments, encourages the workman to report minor injuries for treatment. If, on the other hand, he waits to consult his own physician the injury often becomes septic through neglect and develops into a serious case.

The arguments favoring the selection of the physician by the injured employee may be thus summarized:

1. That the free selection of one's own physician is conceded to be one of man's inalienable rights. The relation between patient and physician is private and personal, and a man naturally desires a physician who can understand him and in whom he has confidence. It is this feeling of confidence in the physician that is one of the most important factors in insuring the patient's peace of mind and hence hastening his recovery, and

2. That physicians selected by the employer or his representative, the insurance carrier, are often employed on a contract basis. This means, often, inefficient treatment and a tendency to minimize the injury and rush the employee back to work as quickly as possible.

Many conscientious employers exceed the re-

quirements of the law in providing medical, surgical, prophylactic, and nursing care, but unfortunately there is an increasing tendency among others to employ physicians on a contract basis. In New York City, there has grown up a very large demand on the part of employers for an organized medical service which will reach all parts of Greater New York, and this demand has been met largely by a number of commercially organized services, not always of the highest type. The largest and most comprehensively organized of these services has no chemical or *x*-ray laboratory facilities, and the men connected with it lack adequate surgical training. These services, however, present certain advantages.

A compromise between the two courses is the so-called "panel system" which has been employed in California. In that State physicians and surgeons competent to treat industrial accident cases are nominated by the State Insurance Fund, and from this panel the injured workman may select the doctor by whom he wishes to be treated. In practice the workman has virtually free choice of his physician, as only the rank incompetents have been eliminated from the panel. This scheme is much discussed in other States, but it scarcely offers a solution of the problem, for in the preparation of the "panel" the State Fund hardly possesses the competence to draw sharp lines of distinction between practitioners, except perhaps in small localities. It must needs be very liberal and that means that the average man with insufficient training in traumatic surgery and no adequate office equipment to treat these cases to a conclusion, would receive official sanction. The system, moreover, is open to abuse and political interference with the practice of medicine.

V. Compensation for Medical Services.—The question of medical and hospital fees has, from the beginning, proven a stumbling block to the smooth operation of the law. The law in New York required that all fees and other charges for medical and surgical treatment "shall be limited to such charges as prevail in the same community for similar treatment of injured persons of a like standard of living." Before the passage of the Workmen's Compensation Law, physicians and hospitals frequently treated injured workmen free of charge or for a nominal fee, because of their incapacity to pay the ordinary charges. Many insurance companies interpret the law as meaning that hospitals and physicians should continue to treat injured workmen at a low charge as before, while the doctors are of the opinion that the insurance companies should pay reasonable charges for services rendered.

In order to avoid such controversies, many of the larger industrial plants have established their own hospitals and employ their own physicians. Whereas a great many very good men have started as company or contract physicians, using the experience as a stepping stone from which to advance, they very often cannot afford to stay in the work long on account of the inadequate scale of remuneration that has prevailed.

Twenty-eight States authorize their Compensation Commissions to fix schedules for medical and hospital services. New York is one of these, but in this State the problem is yet to be adjusted. Directly after the passage of the Workmen's Compensation Act, the Compensation Commission drew up a minimum fee schedule as a basis of charges. The insurance companies, however, insisted upon regarding the rates agreed upon as a maximum, and the controversies arising from this difference of opinion caused so much trouble that the State Medical Society has since repudiated the fee schedule.

Practice of determining the schedules varies in different states. In Massachusetts, for example, and for that matter in New York, the reasonableness of the fee is determined by the charge which would ordinarily be made to the injured man in his locality and by the standing of the physician in his profession. Ohio, on the other hand, regards the whole question as an industrial accident problem and compensates medical services on the basis of treatment given, regardless of locality.

British Columbia has been particularly successful in arranging a fee schedule for medical service. This was done by collecting a mass of data as to the fees commonly charged and then in cooperation with representatives of all the medical men of the Province, arriving at a schedule of charges that seems to give entire satisfaction.

The rates in the fee schedule are uniformly somewhat lower than the rates charged for the same service in private practice, but the greater certainty of payment and the fact that no compensation cases are treated free offset the difference in charges. In several States an inquiry has been made to determine the effect of workmen's compensation on physicians' incomes. In general the answers have indicated little change, or a slight increase in income, and very little dissatisfaction was found among physicians on this score.

VI. Measures for Industrial Rehabilitation.—One of the first effects of the Workmen's Compensation law was a marked decline in the number of industrial accidents. Employers found that the use of safety devices was not merely a humane measure, but that it had sound money value in that it secured a lower rate of premium in workmen's compensation insurance. The second most important development under Workmen's Compensation is that of individual rehabilitation.

New Jersey is among the leaders in assisting its industrial cripples to find places in industry. A Rehabilitation Commission was organized in 1919, which cooperates with the Compensation Bureau and with the Employment Service in reeducating the disabled man to new work and in finding him employment in this new field. A compensation case is not considered closed until every effort has been made to improve the injured man's physical condition. To this end rehabilitation clinics are being established throughout the State, the principal ones at Newark and Jersey City, and smaller ones in cooperation with local hospitals. Where it is possible the insurance companies are required to pay for rehabilitation treatment, but if such an arrangement cannot be made, the State pays.

Plans for vocational reeducation are under way in New York State. In 1920 Congress authorized a grant of $75,000 to any State which would

appropriate a like amount for the vocational re-education of industrial cripples, and New York has accepted the provisions of the grant, and will carry out the program under the State Board of Vocational Education. Funds must also be supplied to maintain the worker while he is undergoing vocational training. Money for this purpose is to be obtained from the $900 referred to above paid in by the insurance companies for each worker killed in industry who dies without dependents. It is estimated that these payments will amount to over $200,000 a year. The usual compensation is, of course, paid the injured workman, but additional compensation up to ten dollars a week is also paid to enable as many as possible to take advantage of this opportunity. The State Department of Education is also authorized to provide artificial limbs at cost to maimed workers.

The Industrial Commission of California has made arrangements with the special industrial accident hospital which is conducted under the auspices of the University of California at San Francisco. Although there is no official connection between the University and the Industrial Accident Commission or the Compensation Fund, the work of the University Hospital has been planned with particular reference to the needs and problems of industrial medicine and surgery.

Summary and Conclusions.—The New York Workmen's Compensation Act, though liberal in its provisions, is yet defective in several regards, particularly in its medical aspects.

Only by a generous interpretation of the law has the late Industrial Commission been able to insure to the injured workman medical attention for a period in excess of the statutory limitation of sixty days.

Supervision of the medical and surgical care given is almost entirely nonexistent, even in cases insured with the State Fund.

Organizations of a purely commercial character for the treatment of industrial injuries have been allowed to develop without supervision as to the character and adequacy of the services rendered.

Many of the neuroses resulting from accidents have not been given the treatment necessary to restore the sufferers rapidly to productive usefulness.

The matter of functional reeducation and occupational therapy in connection with the treatment of injured workers has not received the attention which the modern development of this work demands.

The right of the free choice of physician being denied to the injured man under the law, the moral responsibility for insuring to him proper medical treatment rests with the State authority.

The procedure for obtaining the necessary medical testimony from practitioners or hospital authorities needs to be improved and simplified.

The full time requirement for service in the medical positions of the Labor Department and the low compensation paid do not make the positions attractive to the highest grade of physicians which the nature of this work demands.

This survey, which is of a preliminary character, was undertaken at the request of the State Industrial Commission, who realized the deficiencies in the medical and surgical organization for the treatment of industrial accidents. Because of the lack of adequate funds, the Committee could not pursue the study in the detailed and intensive way which this whole subject urgently demands.

Medicolegal Notes.

Expert Testimony as to Permanence of Injury.—The Missouri Supreme Court holds, citing cases from various jurisdictions, that, "while an expert may express his opinion as to whether or not an injury is permanent, his answer, in order to stand the test of judicial criticism, must show that the result which he has indicated will follow to a reasonable degree of certainty. In other words, his opinon is incompetent if based upon a mere possibility as to what may occur in the future." And in a personal injury case, the admission of opinions given by a medical witness to the hypothetical questions propounded to him by plaintiff that a limp the latter suffered from possibly might be permanent, assuming in good faith the party was not putting the limp on, was prejudicial to the defendants and should have been excluded.—Mahany v. Kansas City Rys. Co., Missouri Supreme Court, 228 S. W. 821.

Privileged Communications Between Physician and Patient—Waiver—Burden of Proof.—In a personal injury case, where the injury was to plaintiff's eyes, the Circuit Court of Appeals, Ninth Circuit, holds that for the plaintiff to testify that a doctor treated him and put drops in his eye was not to testify concerning communications made by him to the doctor, and it did not amount to waiver of the privilege conferred by the Arizona statute as to privileged communications, since "testimony that does not recite the communication works no waiver." The question whether the testimony was privileged was held to be a question for the trial court, and it was proper for that court to hear testimony preliminary to determining it. It has been held that, upon a conflict of evidence, the decision of the trial court upon the question of the existence of the privilege must be deemed conclusive, and that the discretion exercised by that court is not the subject of exception. The general rule is that the burden of proof to establish the existence of the privilege rests on him who claims it. But although the burden was on the plaintiff to establish the privilege, and the trial court found the evidence evenly balanced, the exclusion of the testimony was held not erroneous, since there is a presumption that where a physician makes an examination of an injured person the relation of physician and patient exists with regard to the examination. (Citing Munz v. Salt Lake City R. Co., 25 Utah; Hager v. Shindler, 29 Cal., 47; Sharon v. Sharon, 79 Cal., 633; Moore v. Bray, 10 Pa., 519; McIntosh v. Moore, 22 Tex. Civ. App., 22.)—Phelps Dodge Corp. v. Guerrero, 273 Fed., 415.

Medical Evidence as to Cause of Tetanus.—In a proceeding under the Michigan Workmen's Compensation Act for compensation for a death, it appeared that the deceased while at work on December 19 stepped on a steel shaving, which entered his foot near the little toe. He worked until December 25, when he became ill and died on December 29 of tetanus. It developed during the hearing in the proceeding that the deceased had on December 1 punctured his foot with an old nail while working in his cellar. It was argued that this might as well have caused tetanus as the later injury. The medical witnesses testified, however, that the deceased died from acute tetanus, and that acute tetanus usually develops in six or seven days after the injury and not longer than nine days. If this were so, the court said that his death must have been caused by the subsequent injury, as the first injury occurred over three weeks before the disease manifested itself. It was shown by cross-examination of the medical witnesses that the nail injury might have produced chronic tetanus, and, had it not appeared by positive testimony that the deceased died from acute tetanus, the argument might have had some force. In view of the evidence, the Accident Board's award was affirmed.—Bresee v. Clark Equipment Co. (Mich.), 183 N. W., 19.

THE THERAPEUTIC UTILIZATION OF SHOCK.

THIS is the title of a section of the monograph by Madinaveita on the subjects of anaphylaxis and colloidoclasis, which has recently been published in Madrid. The author accepts Widal's theory of the colloidoclastic nature of the anaphylactic shock. The term proteinotherapy is somewhat vague and susceptible of different interpretations, but in all forms there is an introduction into the blood of heterologous albumin. The quantity and quality of the protein as well as the route of administration are susceptible of much variation. An intravenous injection of a certain amount of peptone will tend to render the blood incoagulable, but injected hypodermically, the opposite result is obtained. A massive intravenous injection will cause shock, while small amounts injected slowly may be made to immunize against shock. Proteinotherapy, however, is only a chapter of the much larger subject of colloidotherapy, and is not specific. It comprises the prevention as well as the therapeutic production of shock. Proteinic shock may be provoked by injecting the patient's own serum. A short latent interval is followed by the so-called hemoclastic crisis of chills and fever, low tension pulse, and tachycardia, which soon passes off. If a few injections of dilute serum are first practised the shock is much less intense. But the same result may be obtained with colloidal metals, peptone, milk, human plasma, specific antitoxins, and bacterial vaccines. The results in occasional experiences are striking and in bacteriemias the blood may clear up for the time and even in rare instances without recurrence. No such results as these have ever been obtained in medical practice. Seemingly specific through the promptness of the action, it has been learned that this promptness and efficiency are bound up in the colloidal nature of the phenomena; for colloids do not behave like the usual crystalloids of the pharmacopœia.

These results, even if rare in practice, are thought to be so important that the future may witness a pharmacopœia made up very largely of colloids. And since there is rather a colloidal state of all matter than a distinct class of colloidal substances, we are looking forward to a colloidal form for our old crystalloidal remedies and explaining therapeutic results—for example, those of arsphenamine—by a colloidal hypothesis.

These substances which induce colloidoclasis are also regarded as nonspecific antigens which induce the formation of antibodies and make immunity possible. In artificial bacteriemias we may see a rapid bacteriolysis the nature of which is not yet entirely clear. It may be an exaggeration of ordinary leucocytosis in which much lytic material escapes from the white corpuscles or it may be due to adsorption of the bacteria to the colloidal particles injected. But despite the brilliancy of the occasional result we are as yet quite unable to control the treatment by selecting the optimum conditions of colloid, dose and precise manner of exhibition.

ARTHROPATHIES FOLLOWING FRACTURES NEAR THE JOINTS.

A JUXTAFRACTURAL arthropathy is occasionally the consequence of too prolonged immobility and it is always increased by an exaggeration of this necessary treatment. The condition is a serious matter in elderly subjects, arthritics, alcoholics and in all persons infected by the gonococcus, staphylococcus, or tubercle bacillus. The prognosis of the fracture itself becomes a secondary matter when the juxtafractural arthropathy develops into ankylosis. Hydrohemarthrosis is the natural initial lesion of this morbid process. The intraarticular exudates therefore present less importance than plastic infiltration of the tendons, fibrocartilage, and dense cellular tissue which reinforces them in the entire circumference of the joint. Sclerous transformation of all these fibrous structures will invariably end in the so-called fibrous ankylosis. In these same periarticular areas the osteoblasts extend beyond the bone surfaces and form stalactites whose grouping will set up a definitive osseous ankylosis.

Pain rarely attracts attention at the onset of a juxtafractural arthropathy, and for this very reason the joint should be attentively examined before the patient complains of pain. A hydrohemarthrosis is usually painless, as it causes but a slight distention of the articular synovial membrane. The infiltration of the fibrous tissues can be recognized by the effacement of the regular form of the parts, the doughy consistency of the structures involved, and, above all, by the decrease in the amplitude of all the movements of the joint.

Juxtafractural arthropathies can be forestalled if immobilization of the limb be interrupted every four to twelve days, according to the case, in order to intercalate, with all necessary precaution, a séance of systematic mobilization by very few maneuvers. When a fibrous ankylosis has formed, it can be somewhat improved by energetic massage and the application of rubber band compression of short duration and local in its effects. The adhesions can be broken up by forcible maneuvers, fixing the root of the limb and taking all necessary

care for avoiding rupture of the callus. The séances of rupturing the adhesions are to be followed by immediate immobilization of short duration. The adjuvant measures consist of methodical massage of the muscle masses connected with the joint involved, as well as by hot douching, local hydromineral baths, and vapor baths. It is always proper to resort to gymnastics and mechanotherapy. A juxtafractural arthropathy ending in bony ankylosis is usually looked upon as a definitive condition; it is this complication which constitutes a real infirmity and it is on this account that fractures near the joints have a really serious prognosis.

ARE DOCTORS EASY MARKS?

THE attitude of those individuals known as "business men" toward physicians is somewhat ambivalent. On the one hand, men of affairs bring their most intimate problems, physical and psychical, to the family physician and are guided by his advice, not only in the regulation of their individual economy, but often even in their domestic relations. On the other hand, when it comes to business affairs, this same wise counsellor is presumed to be either too good-natured or too imbecile to take care of himself; no one in his senses, for example, would think of making a physician executor for an estate. Now and then the name of such a one is found on a list of bank directors, but only because its owner is well-known in the community and his name adds a dignified touch to the stationery.

Any practising physician knows that if he were to read carefully the investment circulars which reach him through the mails he would have time for little else, and if he could realize only one-tenth of the promises made therein, implied or otherwise, he could give up his practice entirely. We can imagine the promoters of any new wild-cat scheme gathering about the mahogany, planning their sucker list. "Well," says one of them, "we have around 150,000 to start with, anyway," and he pats the medical directory close at hand.

As an instance of the schemes which are considered sufficiently plausible to persuade a physician to part with his funds, we note the recent experiences of some of our British colleagues with a certain enterprising young man. This individual represented himself as an insurance agent, but added to the usual line of patter a broad hint that if the doctor took a policy in his company he, the agent, would be able to give him a number of examinations to make. Some physicians were too busy to listen to this siren song, and were saved, a few were suspicious and held off, but many fell a prey to the glib "agent" and paid the first premium on a policy which never arrived. One physician learned of the deception only when he was hurt in an automobile accident and wrote to the company for compensation. The only compensation he received was the knowledge that it is dangerous to pay out cash to smooth-tongued strangers.

If we come to analyze this popular estimate of the physician as an easy mark; it would seem to be based on three things: First, his income is somewhat vaguely regarded by the thoughtless as coming under the category of easy money; secondly, he is supposed to have at least sufficient money to have some to invest, and thirdly, he is regarded as essentially unbusinesslike.

Possibly there is some justice in this last indictment. If so, it is probably due to many causes which are perhaps too familiar for repetition here. Not the least of these is the confusion which exists in the minds of certain of the laity, between regard for ethical standards and lax business methods. While it is unfortunate that the practising physician's unwillingness to adopt the measures of a cheap credit store should be exploited by unscrupulous patients, it is probably better in the long run to hold to the old standards. There is no necessity, however, for him to become a prey to swindlers. If he would take each $500 or $1,000 or $10,000 to his banker and invest it exactly as the latter advises he would soon lose his reputation as an easy mark. Until he does so, let him not ridicule the layman who buys patent medicines instead of consulting a physician.

HEMOCLASTIC SHOCK AND THE CUTIREACTION.

A FEW years ago some American authors, notably Walker, brought the cutireaction into association with anaphylactic asthma. Thus the sensibilizing substance of the asthmatic crisis could be ascertained by means of cutireactions. Jacquelin and Richet, junior, of France then took up this line of investigation and wrote of cutireactions and subcutireactions in this connection. At present the subject is under investigation in the Medical Clinic of the University of Geneva, and Schiff of this clinic has reported on it briefly in the *Revue médical de la Suisse romande*, for August, 1921, xli, 8. The French authors adduce the fact that merely practising the cutireaction may cause, in addition to the local manifestation, a general one in which asthma, edema, diarrhea, or other anaphylactic phenomenon may be produced. In such cases one speaks of "asthma without asthma," etc. The introduction of an infinitesimal quantity of the sensitizing substance is sufficient for this purpose. The intolerance of the organism to the special substance is not extinguished by infinitely small amounts. The reaction due to the entrance of this substance is manifested incidentally in the blood by the hemoclastic picture which is set up. It enters the blood during the act of scarification in practising the cutireaction. One may suppose that the protein matter which is responsible passes at once into aminoacids as the result of a pseudodigestive process. If the subject is fasting at the time of the test the reaction in the blood is more pronounced. As the writer had finished his short article, he learned that the cutireaction had already been introduced into therapeutics by Pasteur, Valary, Radot, and Hagenau, who sought to desensibilize an anaphylactic subject by varying the act of cutireaction. The antianaphylactic inoculation must be repeated at short intervals.

Autosterilization of Flies.

Ambroise Paré and Mercurialis, two of the greatest medical men of the post-medieval period, believed that the fly disseminated the virus of the plague. Before the germ theory, Raimbert and Davaine accused it of transmitting anthrax. But it was one thing to accuse the fly and another to "get the goods on him." Cao fed germs to maggots and found them in the adult flies, but this and many other researches were interesting rather than convincing. The insect has a very varied flora, and to make researches which will withstand all criticism it becomes necessary to breed a race of aseptic flies. This kind of work is being done at present by Wollman of the Pasteur Institute, according to a note in *La Presse Médicale* for August 31, 1921, xxix, 70. It was shown that the larvæ when contaminated by the ordinary pathogenic germs of human stools, became sterile again with development. Both the pupa and mature insect were found free from contamination. The early experiments in this direction are therefore discredited. The adult fly after contamination with the same bacteria remained infected for a short time—not over three weeks. Apparently they become free from contamination much sooner under natural conditions. This autosterilization comes about by ordinary mechanical means—regurgitation and defecation. Hence in each of its three stages of development the fly can sterilize itself after a short interval. Naturally during its 8 or 10 days of contamination the adult fly may theoretically be dangerous to its human entourage. The doctrine that the fly is dangerous because microorganisms are borne about by its feet is not mentioned in this connection, for the possibility of food contamination in this way has been amply demonstrated.

News of the Week.

Child Health Exposition in France.—The American Red Cross "Child Health Exposition," covering practically every department of child welfare, which has been touring the larger cities of devastated France since May, closed its season the week of October 10 at Valenciennes. During the past five months it has "shown" for periods of two to three weeks in six French cities, Lille, Roubaix, Tourcoing, Cambrai, Douai, and Valenciennes, besides a month in Paris. The attendance at the exposition has averaged about 5,000 persons daily. Several French and American organizations joined with the American Red Cross in providing the various specialized departments. The American Committee for Devastated France, the Bordeaux Training School for Nurses, the French Red Cross, and the Jardin des Enfants, were among the cooperating organizations. A feature of the exposition was the enthusiastic and unanimous support it received from the French medical profession in every city. Every local physician gave his services without charge, and most of them were occupied for nearly half their entire day throughout the period of the exposition, in the arduous work of lectures, examinations, consultations, measurements, and the judging of babies. Ample quarters for the exposition were furnished in each case by the municipal authorities—usually in a public school building or municipal exhibition hall. Each morning hundreds of school children were taken through the exposition by their teachers. It is expected that the exposition will be continued next summer under the exclusive management of the French child-health organizations.

Beer and Wine for Medicinal Purposes.—The Secretary of the Treasury has issued regulations for the manufacture and sale of beer, ale, stout, and porter for use as medicine. No more than a case of twenty-four bottles can be ordered on one prescription, but the prescription can be renewed as often as the physician deems necessary. Wine also may be furnished in amount not to exceed two quarts, but there is no limit as to the frequency of renewal of such prescription. The wine and beer can be prescribed only by a physician licensed to prescribe alcohol, and can be sold on prescription only by retail pharmacists licensed to sell alcoholic liquors.

Sir Harold Stiles at the Philadelphia Medical Club.—A reception in honor of Sir Harold Stiles, Regius Professor of Clinical Surgery in the University of Edinburgh, was held on the evening of October 21. The guest of the club advocated a system of intereducation between the United States and Great Britain, through an interchange of professors and students in the universities of the respective countries.

Smallpox in Wake of Cholera.—A despatch from Riga to the *Associated Press* reports that smallpox has appeared in the wake of cholera, typhus, and famine at Tsaritsyn, in the Russian Volga region. A serious epidemic is raging and compulsory vaccination has been resorted to.

Haiti Passes New Vaccination Law.—A law has been passed in Haiti requiring that the doctor or other person attending the birth of a child shall cause his vaccination within one to three months after birth. Free vaccination is to be provided by the National Public Health Service and the hospitals and dispensaries subsidized by the State. Certificates will be given to those who have been vaccinated successfully and to those who have been vaccinated six times without result. Vaccination must be repeated every seven years.

The First Public Surgical Operation Under Ether.—Exercises to commemorate the seventy-fifth anniversary of the performance of the first surgical operation under ether in the Massachusetts General Hospital, were held in Boston on October 16. The first demonstration of a surgical operation under ether was given in the Massachusetts General Hospital on October 16, 1846, when Dr. William T. C. Morton administered the anesthetic and Dr. John C. Warren operated.

United States Marine Hospital in Seattle.—Fort Lawton military reservation on Magnolia Bluff will be recommended by Surgeon General Hugh S. Cumming as the site for a $1,000,000 marine hospital in Seattle. It is proposed to erect an institution that will accommodate about three hundred patients.

Child Relief Exhibit in Vienna.—The American Child's Relief, which is still feeding 400,000 Aus-

trian school children, is giving an interesting survey of its work in an exhibition in the Belvedere Palace in Vienna. Models and photographs show how the work of feeding this large number of children was carried on, and maps and schedules indicate the results of the first medical examination made under American supervision and of subsequent ones.

Bonesetter Must Have License.—In Massachusetts a bonesetter to practise his profession legally must have a license from the State board of registration in medicine. This decision was handed down by the full bench of the Supreme Court of Massachusetts on October 12, in overruling an exception that had been taken by Henry J. Dragon, who was found guilty in Hampden County Superior Court of practising medicine without a license.

Art Exhibit of New York Hospital.—The Society of the New York Hospital, which celebrated its one hundred and fiftieth anniversary with exercises in Trinity Church on October 26, is giving an exhibit of its art collection in the New York Public Library, at Fifth Avenue and Forty-second Street, during the week following the celebration. More than fifty portraits will be exhibited, several by well known colonial artists, besides a large number of prints and numerous early medical books. Among the portraits which will be publicly shown for the first time are those of Dr. Samuel Bard, Dr. Valentine Mott, Dr. David Hosack, Dr. John Cummings Cheesman, and Dr. Samuel L. Mitchell, all of whom have been prominently associated with the hospital.

The New York Electrotherapeutic Society will hold its next meeting at the New York Academy of Medicine on Wednesday, November 2, at 8.30 P. M. Dr. G. Betton Massey of Philadelphia will read a paper on "Rhythmic Electric Waves in Gynecology," and Dr. Barton Cooke Hirst of Philadelphia on "The Uses of Electricity in Conditions Peculiar to Women." All physicians are invited.

Chilean Scientist Claims to Have Discovered the Smallpox Germ.—According to a despatch from Santiago de Chile to the *New York Times*, Dr. Atria, chief bacteriologist of the Chilean Institute of Hygiene, claims that he has discovered the pathogenic microorganism of smallpox.

Open Clinic Day in Brooklyn.—National Homeopathic Clinic Day, set apart by the American Institute of Homeopathy as an occasion when the public is invited to see what the doctors are doing in their clinics, was celebrated on October 18. This idea had its inception in Brooklyn and was celebrated by several Brooklyn hospitals. In the evening there was a mass meeting to which the public was invited and addresses were made by Drs. Royal S. Copeland of New York and H. L. Northrup of Philadelphia.

Hale and Hearty at 106 Years.—Robert Barnabe of Ottawa, Canada, was 106 years old on October 10, and performed his chores about the house as usual. His mother lived to be 110, he has a sister 93, and a brother 94 years of age, both hale and hearty.

Comparative Mortality Rates of New York and Large Cities of Europe.—The New York Health Department has made this statistical study which shows that of the cities of western Europe Florence, Italy, has the highest death rate, 20.48 per 1,000 population, as compared with a rate of 11.07 for the city of Amsterdam, Holland, with a population more than two and one-half times as great as that of Florence. The second highest death rate is that of Vienna, 18.56, due to the exceedingly high death rate from pulmonary tuberculosis and the high death rate among infants under one year of age. Death rates of other cities are as follows: Liverpool, England, 16.44; Berlin, 16.04; Hamburg, 13.83; Düsseldorf, 13.20; Cologne, 14.11; Leipzig, 14.17. The English cities of Birmingham, Bradford, and Manchester show the low rates of 12.54, 13.31, and 12.99, respectively. Paris shows the rather high rate of 14.83. New York and London approximate each other very closely, these being, respectively, 12.93 and 12.65.

American Pharmaceutical Association Makes Research Grant.—The annual grant of the American Pharmaceutical Association has been awarded to Professor David I. Macht of Johns Hopkins University, Baltimore. The grant is the income of $20,000, to be used by Professor Macht for the continuation of his researches on certain synthetic compounds which have a sedative action and have successfully replaced opium. Dr. Macht will give special attention to the study of the benzyl compounds as related to the production of local anesthesia.

Hospital Notes.—The maternity department of the St. Francis Hospital, San Francisco, housed in a new addition to the building, was formally opened on October 5. The new department provides sixty-five beds.

Work will be started at an early date on the new Robert H. Crozer Hospital at Chester, Pa.

Construction of the Shriner's Hospital for Crippled Children in San Francisco, recently authorized by the Hospital Committee of the order, will begin within a few weeks. The edifice will cost $225,000. It is one of five similar institutions to be erected in various cities.

The Beebe Hospital at Lewes, Del., was formally dedicated on October 20.

Ground will be broken for the new Jamaica Hospital in the Borough of Queens, N. Y., in the latter part of October. The new building will be erected on Van Wyck Avenue, where it will be centrally located for the convenience of Woodhaven and Richmond Hill as well as Jamaica.

Dr. Clyde LeRoy Deming has been appointed assistant professor of surgery in charge of the urological department at the Yale Medical School.

Dr. George Herbert Ramsey, formerly of New York, has been appointed deputy commissioner of health in Michigan.

Professor A. Lorenz of Vienna expects to visit America at the end of the present month. His proposed visit is intended to mark his appreciation of what America has done for the children of Vienna. He states that he intends to offer his personal professional services to the children of poor parents who may require his attention and surgical help.

Dr. F. F. Williams of Canton, N. Y., has been elected president of the St. Lawrence County Anti-Tuberculosis Society.

Dr. Stephen Smith of New York will receive a gold medal on November 14, when the American Public Health Association meets. The medal will record Dr. Smith's active participation in the affairs of the society which he founded fifty years ago.

Dr. C. E. Beeman of Grand Rapids, Mich., has sailed for India for the purpose of studying cataract in that country where this condition is very prevalent.

Gifts and Bequests.—The new Fifth Avenue Hospital, New York, has received a gift of $20,000 from Mrs. E. C. Converse of Greenwich, Conn., and one of $60,000 from an anonymous donor.

By the will of the late Emily Dutilh of Philadelphia bequests are made as follows: Episcopal Hospital, $10,000 for the endowment of two beds and $500 for the erection of two tablets as memorials for the testator's father and mother; Woman's Hospital $5,000, American Oncologic Hospital $3,000, Home for Incurables $3,000, Visiting Nurse Society $3,000, Children's Seaside Home at Atlantic City $3,000, Seaside Home for Invalid Women at Atlantic City $2,000, Children's Hospital $1,000, Home of the Merciful Saviour for Crippled Children $1,000, Christ Home for Children at Angora $1,000, Frederick Douglas Memorial Hospital $500.

Vacancies for Physicians at Jewish Memorial Hospital.—At a meeting of the Board of Directors of the Jewish Memorial Hospital, New York, on October 10, it was decided to increase the staff of the hospital. An opportunity is presented to physicians residing in the Washington Heights and Inwood sections to affiliate themselves with this institution. Physicians desiring to become associated with the institution should address the Jewish Memorial Hospital, 2076 Fifth Avenue.

Lecture Course for Montclair Physicians.—The Associated Physicians of Montclair and its vicinity, who conducted lectures and meetings last season, announce that they propose to continue these meetings during the coming season. The dates of these meetings are November 28, December 19, January 23, February 27, March 27, April 4, and May 22. A number of well known men are scheduled to speak on these occasions.

Obituary Notes. — Dr. CHARLES L. MCCANN of Brooklyn, N. Y., a graduate of New York University Medical College in 1871, died of heart trouble on October 19, at the age of seventy-four years.

Dr. FRANCIS PELEG SPRAGUE of Boston died suddenly on October 6, at the age of eighty-seven years. He was graduated from Harvard University in 1857. During the Civil War he served as acting assistant surgeon in the United States Army. He was surgeon at the Massachusetts Charitable Eye and Ear Infirmary, a member of the American Ophthalmological Society, and of the Boston Society for Medical Improvement.

Dr. C. ALANSON PALMER, for twenty years a practising physician of Brooklyn, died of pericarditis in Passaic, N. J., on October 17, at the age of forty-nine years. He was graduated from the Baltimore Medical College in 1895.

Dr. MARCUS C. KERR of Wilkinsburg, Pa., died in a local hospital, on October 9, of injuries sustained in an automobile accident. He was a graduate of Starling Medical College, Columbus, Ohio, in 1892. He was fifty-eight years of age.

Dr. ELI DENNY of Nassau, N. Y., a graduate of the Eclectic Medical College of New York in 1888, died suddenly of heart disease on October 4, at the age of sixty-five years.

Dr. JOHN L. JONES, a graduate of the Louisville Medical College in 1872, died suddenly of heart disease in his office in Los Angeles, Cal., on September 29, at the age of seventy-five years.

Dr. FRED C. PURCELL of Jamestown, N. Y., was killed in an automobile accident near Blasdell on October 12. He was a graduate of the University of Buffalo Medical College in 1903, and was forty-four years of age.

Dr. HERMAN A. BRAY of Philadelphia, a graduate of the Medico-Chirurgical College, Philadelphia, in 1898, died on October 12, at the age of fifty-one years. He was a Fellow of the American Medical Association and a member of the Medical Society of the State of Pennsylvania and the Philadelphia County Medical Society.

Dr. CHARLES MILLER FOSS, a graduate of Hahnemann Medical College and Hospital, Philadelphia, in 1868, died of Bright's disease at his home in Bangor, Me., on October 9, at the age of seventy-four years.

Dr. ISAAC DARR of Morley, Mich., a graduate of the Medical College of Fort Wayne, Ind., in 1880, died suddenly on October 15, at the age of sixty-seven years.

Dr. GUSTAVUS A. ASCHMAN of Wheeling, W. Va., a graduate of the University of Zurich, Switzerland, in 1884, died on October 2, at the age of sixty-one years.

Dr. GEORGE E. WASHBURN of Augusta, Me., a graduate of Bowdoin Medical College in 1898, died of pneumonia on October 14, at the age of forty-six years.

Dr. DANIEL S. GROSSMAN of Leighton, Pa., a graduate of the University of Pennsylvania School of Medicine in 1877, died suddenly on October 6, at the age of seventy-two years.

Dr. JOHN F. HARRIS of La Crosse, Wash., died in a local hospital on October 6, at the age of sixty-nine years. He was graduated from the Medical Department of the National University of Arts and Sciences, St. Louis, Mo., in 1882.

Correspondence.

THE RED CROSS TEACHING CENTER FOR THE INSTRUCTION OF DIABETICS CONCERNING DIETS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The object of this communication is to inform physicians of New York concerning the activities of the Red Cross Teaching Center for diabetics, at 24 Fifth Avenue, corner of Ninth Street. The chief aim in the treatment of diabetes mellitus is to secure for the patient a diet suitable to his individual requirements. And the prime difficulty in this endeavor is the instruction of the patient so that he can carry out explicitly the directions of his physician. This instruction of the patient in the execution of his physician's orders is the func-

tion of the dietitian of the Teaching Center. For all cases of diabetes, excepting the milder types of the disease, it is necessary not only to prohibit some foods entirely but also to place definite restrictions on the amount of all food eaten. A restriction in amount requires a method of measurement and it also requires a knowledge of the chemical composition of foods of which most patients, and many physicians, are ignorant. Few physicians except specialists command the services of dietitians and few patients are able to pay for these services. This is the need the Teaching Center is endeavoring to supply.

The way in which the Center actually functions in practice is illustrated by our methods in the wards of the New York Hospital. After the initial steps necessary to free the urine of sugar and reduce the blood sugar, we commence the process of building up gradually a suitable diet. The patient is then sent to the Center daily for a few elementary instructions necessary, because the majority of patients are completely ignorant. As the time for the patient's discharge from the hospital approaches, the dietitian of the Center is informed of the patient's tolerance and the composition of his present diet. The diet is prescribed like a drug, for example: Protein 60 g., Fat 100 g., Carbohydate 40 g. The dietitian at the Center instructs the patient how to transform this prescription into a daily food allowance. Scales are not used; instruction is all carried out in units of cupfuls and tablespoonfuls. In this way, when the patient is discharged he is fully informed, not only as to the character of the food which he may eat, but also the amount of food which is permitted. The patient then may be referred back to his physician or, if he have none, the course of his disease may be observed by having him report back to the hospital periodically in the Follow-Up Clinic.

A small number of physicians in the city have availed themselves of the services of the Teaching Center for their poorer patients, but not as many make use of it as should. The largest number of diabetics are treated, of course, by the general practitioners and the services of a dietitian would be to them an especial advantage. In a few instances patients have been sent to the Center with very vague directions from the physician as to the diet which he desired the patient to have. Of course it is not sufficient to indicate that the patient needs a diabetic diet; this meant something fifty years ago but it does not today.

In handling new cases, or cases that have not been adequately treated, a physician's first desire is to free the urine of sugar, if that can possibly be done. The Teaching Center may be of great service in aiding the physician to do this. He might, for example, prescribe a relatively low diet in respect to carbohydrate and fat, leaving the protein ratio adequate only for the weight of the patient—the usual allowance, a gram per kilo. The dietitian would teach the patient how to make this restricted diet and the doctor could observe the result for the next few days or weeks, as he saw fit. If he desired, it might be interpolated by fast days, or a period of fast, or if he wished a sharp curtailment of the diet in respect to protein, this could easily be effected by eliminating certain articles of food for a definite period. It is probable that by manipulation of the diet in this way the majority of patients would be free of glycosuria after a brief interval. The physician could then direct the dietitian to increase the diet in respect to some one food ingredient, either carbohydrate or fats, for example. In this way the patient would be correctly treated in the first place and the physician would be constantly conversant with exactly what the patient was receiving in his diet. Very few physicians have the time or the interest to write out laboriously a list of diets representing variations in carbohydrate, fat, and protein and the caloric values of these diets. By an intelligent use of the Teaching Center the necessity for this is done away with.

In the case of a few very severe diabetics it probably will not be possible for physicians to conduct the initial steps of the treatment in the way outlined above, although the attempt might be made. Such cases usually can be handled only in the hospital during the first few weeks of their treatment.

The functions of the Teaching Center are not confined to the teaching of patients, or relatives of patients, suffering from diabetes, but includes all forms of dietetics. I have put the emphasis on diabetics because the treatment of that disease is in a large measure standardized. There is no dissent among intelligent physicians as to the ultimate aim to be sought and, in general principles, the methods of treatment.

NELLIS B. FOSTER, M.D.

NEW YORK.

A CASE OF MONKEY GLAND TRANSPLANTATION.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In justice to the New York Diagnostic Clinics and Dr. I. Mufson, who made an electrocardiographic examination of Mr. Irving Bacon at the request of Dr. Thos. W. Edgar, we trust that you will give publicity to the following facts:

Upon Oct. 15 Dr. Edgar phoned the clinic requesting that we make an electrocardiographic examination of one of his patients. The patient's name was not mentioned. Later the above named patient, accompanied by Dr. Edgar, appeared for an electrocardiographic examination. This was performed, but the report had not been sent, when the following day there appeared in the Sunday edition of the *New York American* an article relative to the operation upon Mr. Bacon, in which it was stated that "Dr. I. Munson of the New York Diagnostic Clinics, on West 72d Street, would prepare the cardiogram." It was Dr. I. Mufson, not Munson, who made the examination.

Upon the appearance of this undesired and what we consider unethical publicity, a letter was sent to Dr. Edgar, of which a copy is enclosed.

Dear Dr. Edgar:

Enclosed please find check for $6.00, being refund of the fee for an electrocardiographic examination made of Mr. Irving Bacon.

These instructions are being followed inasmuch as an unauthorized and what is considered an unethical use of the names of both this institution and the physician making the examination, has been made.

Had we been informed that newspaper publicity

would be given this examination, we would have refused examining the patient.

We believe further comment on the case is unnecessary.

S. UNDERNDORFER,
Secretary, New York Diagnostic Clinics.

OUR LONDON LETTER.

(From Our Own Correspondent)

LONDON, Oct. 6, 1921.

Post-Graduate Medical Education in Great Britain.—The report of the Post-Graduate Medical Committee appointed by Dr. Addison, the Minister of Health, is issued now in pamphlet form. The report begins by summarizing the provision made for post-graduate medical education in the past. It may be said that Sir Jonathan Hutchinson, that man of remarkably original mind, was the pioneer in this matter in the early nineties, he established the polyclinic in London, and as is well known more recently the Fellowship of Medicine has attempted to carry on the good work and to render the necessary facilities more accessible. However, the report makes it perfectly clear that the present organization is far from satisfactory and that much more must be done ere suitable provision can be said to exist. Attention is rightly drawn to the fact that the continent of Europe, and Vienna in particular, has for a long time been regarded as the place where medical graduates can most easily secure what they need in the way of general and specialized instruction. The report lays emphasis upon the fact that an opportunity now presents itself for providing in this country a center at which students from overseas, whether from our own colonies, from America, or from foreign parts may find facilities for post-graduate medical instruction and that London, with its unique supply of clinical material and its 38,000 beds seems singularly well placed to provide such a center. Another interesting feature of the report is the suggestion somewhat emphatically put that cottage hospitals should be used to a greater extent than at present for increasing the experience and efficiency of general practitioners. The report states that it is desirable that all practitioners within the area served by a cottage hospital should have the facilities, if they wish, to bring their own cases into the wards and to attend them there. In this way better treatment would be secured for the patient, while the general practitioner would have an opportunity of consulting with his professional colleagues. The main recommendation made in the report, however, is for the establishment of a Central Post-Graduate Hospital and School which should be devoted to post-graduate work. It is not recommended that a new hospital should be built. The hospital should be one equipped in an up-to-date fashion with at least 300 beds, with a fully developed out-patient department. Associated with this central hospital and school would be the great special hospitals of London. It is suggested that one of the existing undergraduate schools might be converted into such a center. The committee also recommend the institution of a central office, which would link up post-graduate study in Great Britain, and in due course with that of the continent of Europe and America. This central office should be in charge of a whole-time principal officer and its committee of management should be responsible for the organization of the system as a whole. Attached to, and as part of, the central office, there should be provided social facilities in the shape of reading rooms, a restaurant, and a library of periodicals. A hostel for the convenience of medical men attending the courses from a distance would also be desirable. The suggestion is further made that public health postgraduate work should be concentrated in an Institute of State Medicine connected with the University of London and under its administration. The institute, in addition to providing instruction in public health, would furnish courses in forensic medicine, in toxicology, and in industrial medicine. It would accommodate students from overseas and foreign countries and create a link between them. The scheme proposed and sketched above would involve an annual charge of £28,000. Support from local rates will not be expected. Inasmuch as the School and Institute are proposed as constituent parts of the University of London, they will be eligible for inclusion in the list of grant-aided university institutions for which money is already provided by the National Treasury through the University Grants Committee. If this scheme were carried out in its entirety quickly there would be a chance of London becoming a great or even the great European medical postgraduate center. But, while schemes have been put on paper not very much has been done to bring them to fruition. For longer than two years the matter has been discussed and still lags in a disappointing manner. There appears to be a lack of enthusiasm among the bulk of London practitioners with regard to the scheme and also no doubt a lack of money to forward it to completion. But when one hears that Vienna, notoriously the poorest large city of Europe, is again becoming established as the chief European postgraduate center and that Americans are flocking thither to put a coping stone on their medical and surgical knowledge, one cannot but fear that London will miss the opportunity of being regarded as the Mecca of overseas postgraduate medical students.

Opening of the Medical Schools.—Westminster Hospital Medical School opened for the winter session on Sept. 30 last. Dr. Adolphe Abrahams, assistant physician to the hospital, gave the introductory address, dealing with advantages and drawbacks of a small medical school and with the question of coeducation in medicine. The speaker thought that one feature of large medical schools which tended somewhat to detract from their value was the great attention paid to athletics and to the social aspect generally. The smaller schools not having many distractions of this kind were able to concentrate more thoroughly on medical study and training. But the part of the address of the greatest interest was that in which he discussed the problem of women medical students. It was pointed out that on account, mainly, of the great rush of students to the larger schools few women were admitted and for the most part the large schools had not yet opened their gates and offered the same conveniences for

study to women students. On the other hand, the smaller schools were not in the same position as the larger schools, with the privilege of picking and choosing, and if the latter had had to refuse admission to women students these had naturally turned to the smaller schools. Dr. Abrahams was unable to make up his mind as to whether co-education in medicine was desirable and drew attention to the fact that, teachers of profound experience had not hesitated to express their conviction that it was not possible to lecture, or demonstrate with equanimity on certain subjects to a mixed audience, although no embarrassment occurred if the class at one time were wholly young men or young women. He had no intention of proceeding with a discussion of this nature, but it was clearly necessary to mention it as one particularly affecting the smaller school, whose male entries might in consequence be prejudiced.

At the opening of King's College Hospital, on Sept. 30 last, the Dean of the Medical School, Dr. H. Willoughby Lyle, in his annual report referred to the closing of 160 beds, and pointed out that in spite of this they had 241 unqualified students, the largest number they ever had. Included in this number were ninety-three women.

The opening of the winter session of the London Royal Free Hospital School for Women took place on Oct. 3 last. The Dean, Miss Aldrich-Blake, who presided, welcomed the sixty new students and said those of them who read the newspapers might be feeling a little anxious as to the prospects of women in the career they were adopting. The admonitions, which largely came from men, seemed to take the line that if there was a great deal that wanted doing women might come and do it, but if the work were less in amount or less pressing, then women should retire to the domestic or other occupations. The workers of the world might roughly be divided into two classes, those who did some sort of productive work and those who served the producers. Undoubtedly, in medicine they were among those who served, and it appeared to her to be the part of the public alone to choose by whom they would be served. So far as her own experience went, she rarely found that those who were good and industrious lacked opportunities to develop their talents. Dr. Louisa Martindale delivered the inaugural address and referred to recent criticisms in the press and elsewhere as to the need for women doctors, their capabilities, and the attitude of the public toward them. Dr. Martindale dealt with several points in the recent report of the principal medical officer of the Ministry of Health, and pointed out to the students that unless there was a very radical change during the next few years, some of them would later on find their life work in service connected with national health insurance. She believed many of the students of to-day would be the radiologists of the future, having under their care many cases of cancer that to-day they were attempting to treat surgically. It was there in the treatment of cancer that women doctors would be most useful, and, if for no other disease than this, the existence of the woman doctor seemed justified. Their only check was their inability to get appointments on the honorary staffs of some of the more reactionary of the general hospitals. This had necessitated the establishment of women's hospitals, but with the further development of the modern hospital they might hope that this disability would die a natural death, and that gynecology would fall more and more to the woman doctor. In conclusion, Dr. Martindale said that the present-day student would never reach anything like her ideal of being an efficient and useful doctor unless she knew something of the world in which she and her patients lived. She must read widely and keep in touch with current politics, literature, and municipal life. She must remember the importance of good manners and suitable and pretty clothes, for it was unnecessarily annoying to a patient to have to look at slovenly things. Character, in the end, would carry further than brains. She had no doubt that the next few years would see many developments in the modern hospital, but whatever the development might be, she was sure there would be ample opportunities for the woman doctor.

Reduction of Infantile Mortality.—Dr. Amand Routh, consulting obstetric physician at Charing Cross Hospital, delivered, on Oct. 3 last, a lecture on "Antenatal Hygiene" in Morley Hall, Hanover Square, London, in which he paid a tribute to the work of the National Association for the Prevention of Infant Mortality and for the Welfare of Infancy under the supervision of its secretaries, Dr. Eric Pritchard and Miss Halford. He said in part that the National Association for the Prevention of Infant Mortality, with the financial assistance which the Ministry of Health had given, had been the main agency in achieving the great reduction in infant mortality and the better health of infants which was the feature of the past decade. In 1920, of 76,552 infantile deaths, rather less than in the previous year, nearly 10,000 occurred in the first twenty-four hours of life and 11,000 in the next six days. It amounted really to 20,900 deaths in the first week or over one-fourth of the infantile deaths for the whole twelve months. In the first month there were 33,600 deaths or well over one-third of the total for the year. In order to lessen that great loss to the nation he suggested that every expectant mother should get medical advice and that the state should help in necessitous cases, so that the expectant mother might be able to cease industrial work and have financial help as well as medical supervision.

Anthrax from Shaving Brushes.—There has occurred recently a death near London from anthrax contracted from an infected shaving brush. The infected brushes are believed to come from Japan, and, although the importation of such brushes was forbidden by the Government more than a year and a half ago, it is feared that there still remain in the hands of retailers large numbers of shaving brushes of Japanese origin. The Ministry of Health advise the following method of disinfection. The brush should be (a) thoroughly washed with soap and warm water containing a little washing soda and then allowed to stand for half an hour in warm water containing a little soda; (b) placed in a warm solution of formalde-

hyde for half an hour; (c) allowed to dry. However, complete sterilization of the brushes is impracticable, and this method of sterilization does not affect spores imbedded in the handle of the brush.

Obituary.—Dr. Wallis Chapman, the first woman doctor of Lincoln, has died after a prolonged illness in her fiftieth year.

Dr. John Ward Cousins, a well-known medical practitioner, died in Portsmouth on Sept. 22 last. In 1853 he entered as a medical student at St. Thomas's Hospital. In 1856 he gained the Cheselden medal and qualified M.R.C.S. Eng. and L.S.A. In 1858 he graduated M.B. at the University of London, taking the degree of M.D. in the following year. In 1859 he became F.R.C.S. Eng. After residing in London for a short time, in 1863 he was appointed to the staff of the Royal Portsmouth Hospital and to the Portsmouth Eye and Ear Infirmary. In medical politics Dr. Cousins took an intense interest. He was for many years honorary secretary of the Portsmouth division of the British Medical Association and was president of the association on the occasion of its visit to Portsmouth in 1889. He wrote on a wide range of medical and surgical subjects and invented a large number of surgical instruments, for which he was awarded a British Medical Association prize and a gold medal at the International Inventions' Exhibition.

Capt. Robert A. Flynn, F.R.C.P.I., of Dublin, gynecologist to Drumcondra Hospital, died recently in Dublin after a painful illness. He accepted a commission in the beginning of the war in the British Royal Army Medical Corps and accepted re-engagement after the armistice. He had suffered for some time from heart disease, but his sudden death came as a shock to the large circle of friends in Dublin.

5. Procidentia Recti. T. Chittenden Hill.
6. Pituitrin in the Third Stage of Labor. Roy J. Heffernan.
7. Sarcoma of Bone. Torr Wagner Harmer.

2. Report of the "Schick" Test Campaign.—Joseph Garland presents the results of the campaign that has been carried on by the Committee on Public Health of the Massachusetts Medical Society, in the interests of diphtheria prevention and control. The committee decided that it would be of value in furthering the Statewide control of diphtheria to carry on a series of demonstrations of the Schick test, with an explanation of its value and that of the subsequent administration of toxin-antitoxin to persons in whom the Schick test showed susceptibility. The writer undertook this campaign. Three hundred and eighty Schick tests have been performed and demonstrated before groups of physicians and nurses in fourteen of the large cities of the State. Of these tests 52.8 per cent. were positive, 47.2 negative, 7.1 per cent. combined, and 22.1 were pseudoreactions. These tests have therefore shown that there exists, among the more educated classes, at least, a greater susceptibility to diphtheria than has been previously supposed. In order to effectively control diphtheria, all persons over six months of age in the community should be immunized (if under six years of age), or should have their susceptibility to diphtheria determined by the Schick test, and, if proved to be susceptible, should be immunized.

3. Mortality in Placenta Prævia for the Last Twenty-five Years at the Boston Lying-In Hospital—Foster S. Kellogg has analyzed 218 cases, including complete, partial, and marginal prævias, considering them in groups for the five-year periods. The maternal mortality in these five-year periods was 17, 15, 24, 20, and 6 per cent., respectively. He concludes that they have improved their personal statistics in placenta prævia by a more frequent resort to conservative methods of delivery, especially Braxton Hicks' version and the uses of the bag, and that, while other factors have contributed to their better results, this is the most important one, and that one or the other of these methods should be used, to the exclusion of manual dilatation and extraction. He feels that these conservative methods of treatment are still insufficiently regarded by the physicians in the community. During the last five-year period bags and Braxton Hicks' version were used in 57 per cent. of the cases. Since some 20 per cent. of hospital cases get to full dilatation by the time they are seen, Kellogg feels that during the next five-year period 70 to 75 per cent. of placenta prævia cases should receive this treatment, and that with this change will come still further improvement in results. Six per cent. mortality he considers too high; it is still higher than the old German figures with bipolar version.

6. Pituitrin in the Third Stage of Labor.—Roy J. Heffernan gives the results of his experience with 100 patients observed at the Sloane Hospital for Women, New York City, to whom 1 c.c. of obstetrical pituitrin was administered hypodermically immediately after the delivery of the baby. He concludes that pituitrin administered at the beginning of the third stage of labor is effective in aiding a prompt and complete detachment and expulsion of the placenta and membranes. Tetanus uteri with incarceration of the placenta does not occur from the careful use of pituitrin in the third stage of labor. Pituitrin tends to prevent relaxation of the uterus and post-partum hemorrhage during and after the third stage of labor. Manual removal of an adherent placenta should not be attempted until at least three doses of pituitrin have failed to produce attachment. Rarely one sees a case of adherent placenta which will not respond to pituitrin. In this type of case its use obviates the danger of hemorrhage until the placenta can be removed by other methods. It was thought advisable to give ergot after the third stage to only 20 per cent. of the patients who received pituitrin, whereas in 45 per cent. of the control cases it was thought necessary.

1. The Symptomatic Treatment of Pneumonia.—H. J. Means and A. L. Barach assert that in spite of the more brilliant results obtained with specific remedies, it cannot be denied that symptomatic treatment has met with no small measure of success. The rational symptomatic treatment of pneumonia must be based on a clear understanding not only of the morbid anatomy

but also of the morbid physiology of the disease concerned. In pneumonia the outstanding feature is the respiratory battle. A great strain is thrown upon both respiratory and circulatory mechanisms. The respiratory strain results from the circumstance that the pneumonia patient is simultaneously confronted with a necessity for a greater pulmonary ventilation than under normal circumstances, and a pulmonary bellows of reduced efficiency with which to accomplish it. He has a greater ventilatory demand and at the same time a decreased ventilatory supply. A number of factors contribute to this vicious state of affairs. Increased metabolism, acidosis, deficient circulation, and anoxemia may increase the demand for ventilation. At the same time, decreased vital capacity due to consolidation, edema or pleural pain, or abdominal distention may decrease the capacity of the pulmonary bellows. We can directly meet some of these indications. Acidosis, if present, we can correct by alkali administration. Alkali administration also may be hoped to help the nonacidotic case because it raises the bicarbonate level of the blood, which in turn makes it possible for the patient to get along with a reduced pulmonary ventilation. Anoxemia, which is frequently present and which has a variety of injurious effects, may be corrected or relieved by oxygen administration. Both these measures—alkali administration and oxygen administration—must be carefully and intelligently controlled. Bicarbonate should be given only in amounts sufficient to turn the urine alkaline to litmus. If pushed further than this it may do harm by producing alkalosis. Oxygen should be given with one of the modern types of apparatus and often nearly continuously by a specially instructed nurse. Its continuation is to be governed by the effect on the cyanosis and the comfort of the patient. These measures are supplementary to specific therapy. When used, however, they may be expected to spare the patient several avoidable burdens and leave him free to devote his entire energy to the fighting of his infection, thus, theoretically at least, improving his chance of recovery.

4. Treatment of Arthritis: Chemical and Clinical Studies with the Salicylates, Cinchophen, and Neocinchophen.—Arthur F. Chace, Victor C. Myers, and John A. Killian have studied the influence of these drugs in a series of more than 50 cases, in about one-fourth of which the patients were suffering from arthritis. The clinical deductions are based partly on the observations in these cases and partly on observations in a large series in the private practice of one of the writers. They find that in general the salicylate and cinchophen groups of drugs show comparatively little difference in their analgesic, antipyretic, and "uric acid eliminating" effects. It should be noted, however, that this latter term is not sufficiently inclusive, since these drugs also stimulate, to a lesser degree, the elimination of other waste products. There appears to be no relation between the therapeutic efficiency of these drugs in infectious arthritis and their influence on the blood uric acid, a statement which is not generally regarded as applying to gouty arthritis. In the series of cases here reported cinchophen and neocinchophen seem to have a more specific effect in the severe cases of infectious arthritis. The salicylates have the distinct disadvantage of producing marked proteinuria and casts when given in large doses. On this account cinchophen and neocinchophen are the drugs of choice when, for any reason, it seems desirable to favor the kidneys. Furthermore, the latter drugs appear to produce their therapeutic effect through smaller doses. The salicylates have the advantage of being better assimilated by rectum. Cinchophen and neocinchophen, particularly when given with alkalis, are better tolerated by the stomach than salicylates. Since neocinchophen is an ester instead of an acid, there is less need of using alkali than with cinchophen. In fact, when given without alkali, neocinchophen does not seem to irritate the stomach. Although a few cases of marked idiosyncrasy to the salicylates (acetylsalicylic acid), in the nature of an allergic reaction, have been reported, the experience of the writers is that patients are more liable to have vasomotor disturbances of the urticarial type from cinchophen. No serious instances of the latter have been observed.

9. Diagnostic and Therapeutic Aspects of Late Sequelæ of Gastric Surgery: Observations Based on Six Thousand Four Hundred Operations for Chronic Gastric and Duodenal Ulcers.—George B. Eusterman states that out of a total of 6,402 operations of all types for chronic benign ulcer failure to achieve cures made 228 secondary operations necessary. There were 4,793 posterior gastrojejunostomies alone. The causes underlying the recurrence or continuation of painful symptoms are those which Moynihan gives as the chief reasons for failure. Eighty-eight per cent. of those in whom the operation failed, including those who experienced no relief from the operation, had a recurrence of symptoms within one year following the operation. In more than half the patients the pain was left-sided and lower than before the operation. Carcinoma developing on benign gastric ulcer for which a previous gastroenterostomy alone had been performed was found at secondary operation in 23 cases. The writer's experience with the end results of several hundred well-executed pyloroplasties, many performed under favorable circumstances, has not been encouraging. His answer to the charge that gastroenterostomy is an unphysiological procedure is that at least 15 per cent. of all pyloroplasties eventually prepare a rich soil for a highly successful gastroenterostomy. He believes that time and a large experience will temper the present laudable enthusiasm for pyloroplasty. The nihilism with regard to therapeutics manifested by the surgeon in the past is not a flattering chapter in the annals of achievement in the domain of gastric surgery. In more recent years this attitude has changed. Medical management has been discredited, not because the principle is wrong, as the capacity for healing in ulcers is variable, but because the effort was inadequate and the cooperation of the patient was not sufficiently cultivated. Consistent medical management is often superior to poor surgery, and the mortality is practically nil. There is necessity for friendly cooperation between the physician and the surgeon. Unquestionably the best interests of the majority of ulcer-bearing patients are conserved by such combined efforts. In the Mayo Clinic the surgeons leave to the clinicians the preoperative preparation and the details of the immediate and later postoperative dietetics, alkaline therapy, removal of foci of infection, and regulation of the future life of the patient.

10. Observations on Bacillus Botulinus Infection of Canned Spinach.—S. A. Koser, R. B. Edmonson, and L. T. Giltner summarize their observations on 174 samples of canned spinach, taken from suspected lots, as follows: *Bacillus botulinus*, Type A, is able to multiply and to produce its characteristic toxin in canned spinach, although the development of the organism in this food product was found to be somewhat irregular. A temperature of 37° C., as contrasted with room temperature, accelerated the development to a certain extent. When multiplication had progressed readily, 0.5 c.c. of the spinach juice per os proved sufficient to kill guinea-pigs, usually within 18 hours. The growth of *B. botulinus* in canned spinach is accompanied by the evolution of gas as well as by the elaboration of the specific toxin. In only one instance had toxin formation advanced to such a stage as to produce a fatal result, while at the same time gas production either had not occurred or was insufficient to produce bulging of the can. In the 174 samples of canned spinach taken from suspected lots, *B. botulinus* or its toxin was found in six. In every instance the organism was of the A type. These six toxic cans were all "hard swells," and, when opened, the odor was distinctly offensive. The destruction of foodstuffs deemed to be abnormal, either by appearance of the containers or by the odor, should prevent the greater number of outbreaks of botulism.

4. An Experimental Study of Prophylactic Inoculation Against Scarlet Fever.—I. Takahashi presents this preliminary communication in which he describes experiments made on five of his own children. His observations seem to show that prophylactic inoculation against scarlet fever with the blood of a patient, taken before eruption appears and given subcutaneously in an amount of 0.0001 c.c., causes not only no local or general symptoms in man, but protects him from infection. Even an injection given 50 days after inoculation with the blood, and smearing the children's throats with a mixture of blood and throat secretions 115 days after inoculation, did not give rise to the disease. It has been claimed by some investigators that one-third of human beings have a natural immunity against scarlet fever, and perhaps these children had this immunity. Moreover, it has not yet been proved that the dose of blood given in the infection experiments was enough to infect the children. Taking these facts into consideration, the writer says he cannot claim that these results are flawless; but, considering the results which Dr. Kusama obtained with typhus fever, the fact that the experimental objects were of the most susceptible age, and the control monkeys showed the presence of the virus in the material used for the smearing, it seems not an over-statement to say that the experiment strongly suggests the efficiency of prophylactic inoculation against scarlet fever. The writer expects to report later on the effective period of immunity and its time of appearance after inoculation.

7. A Case of Poisoning by Cantharidin.—C. H. Andrews reports the case of a medical student who, out of misplaced curiosity, took at least as much as one-fiftieth of a grain of cantharidin. Three hours later he noticed pain in the left lumbar region, and two hours later noticed blood in his urine. The signs and symptoms were those of a glomerular nephritis. There was no edema, no great reduction in the fluid output. There was hematuria with large numbers of leucocytes in the urine, and moderate numbers of casts, soon disappearing; normal blood urea; normal diastase output; blood sugar on the lower limits of normal at first with a urinary sugar on the upper limits of normal. There was absence of vesication in the mouth and the relatively slight damage that ensued suggests that it was not all absorbed. A remarkable feature of this case was the rapidity with which the condition cleared up after the sixth day. The urine six weeks after taking the drug showed no albumin, no casts, and no red or white cells. His blood pressure, which had risen to 140 in the course of a few weeks, fell to 112. The writer can find no record of any other case in which cantharidin itself has been taken, and reports the case because he thinks it throws a little light on inflammations of the kidney.

5. Standard of Cure in Gonorrhea.—E. R. Townley Clarkson asserts that most practitioners fail to realize their responsibility as to the necessity of subjecting every patient who has suffered from gonorrhea to the most exigent tests. In the application of tests no selective treatment should be meted out to the married man or the bachelor. When the practitioner believes that his patient is cured he should cease therapeutic treatment for at least ten days. During this time provocative treatment should be administered. About five days after the patient is believed to be cured the prostate and vesicles should be massaged. This procedure is sometimes followed by a discharge the result of autoinfection. The provocative measure fully deserves the importance assigned to it by Dr. Malcolm Simpson. During the time that treatment is suspended the patient should consume alcohol, stone ginger beer, or ginger ale; both of the latter beverages possess provocative value, and the patient should be instructed to apply himself to a diet which is highly seasoned. If at the end of the provocative period no untoward results have accrued, a large sound should be passed and the anterior urethra massaged over it. After the removal of the sound the prostate and vesicles should be massaged, and the patient should pass urine. An instillation of silver nitrate, 10 grains to 1 ounce, should be administered and the urethra painted with silver nitrate, 10 grains to 1 ounce. These provocatives will generally oust any lingering organisms. In obtaining specimens for examination massage should be thoroughly done, the vesicles being massaged from above downward. Neglect to massage as much of the prostate as possible will go far to account for those variations in reports which are received from bacteriologists. No one excepting an experienced practitioner should be allowed to undertake the task of procuring specimens for final tests. Clarkson is inclined to think that if a thorough series of efficient clinical, bacteriological, and microscopic examinations are carried out there is no necessity to use the complement fixation test, since in his experience the results of this test cannot be compared to the comprehensive ones of the foregoing in respect to efficiency; in every case it should be regarded as an adjuvant, and not in any sense as a principal means of determining whether a patient is still suffering from gonorrhea. In cases of metastatic gonorrhea he believes it is of greater value. In women the general procedure in respect to provocative treatment is of a nature similar to that which is carried out with regard to men. Both the cervical and urethral canals should be dilated. The patient should be subjected to the provocative application of silver nitrate to the cervix, urethra, the glands of Bartholin, and Skene's tubules. If there is no tubular involvement, then vaccines may be administered, although if the introduction of silver nitrate, etc., has been efficiently carried out they are probably superfluous. In obtaining specimens for examination massage should be applied to both the urethra and the vagina, and the cervix should also be subjected to some form of massage. More tests should be applied to women than to men. It is not advisable to discharge a woman as cured after two or three tests. If she passes the first series of tests a second series should be made after three months.

6. The Sensations as Reflex Manifestations of Disease.—P. T. Herring recalls that in a recent communication, Sir James Mackenzie has put forward the thesis that the early symptoms of disease reveal themselves in a disturbance of the normal reflexes. This hypothesis, arrived at by the members of the St. Andrews Institute for Clinical Research, involves a wider conception of what is meant by "reflex" than the term is usually held to denote. According to this theory the body is regarded as a highly complex and efficient mechanism, the actions of which are coordinated and controlled by innumerable reflexes. In a state of health the reflexes are nicely balanced and in constant play one with another. Symptoms of disease show themselves by a disturbance of balance which in the initial stages may be similar to that occurring in normal physiological conditions, the difference being that in the case of disease the physiological stimulus is absent or is insufficient to account for the altered condition. The most common of the early symptoms of disease are sensations, especially those of exhaustion and pain. The ordinary physiological conception of the reflex finds no place for these sensations, but from a clinical viewpoint they may be regarded as reflex provided one adopts a wider conception of what the reflex really signifies. In the case of sensations the effector organ is the cerebrum, which is to be looked upon as a distinct organ with very definite functions, not the least of which is the translation of afferent impulses into sensations. The cerebrum responds to the impulse and in this case is the effector organ; its response is the sensation of pain, or whatever sensation the afferent impulse evokes. The response by the cerebrum is, as a rule, only one of the results of an afferent impulse. The cerebrum

can act as a receptor; that is to say, it can, in response to an adequate stimulus, initiate a reflex. The perception of a sensation excites a number of special processes, including, it may be, memory, judgment, or other phenomena associated with cerebration. Such activity may result in an impulse which, from the point of view of the present argument, must be regarded as afferent in that it goes to the reflex centers. It is there coordinated and distributed to the effectors. In this sense the conditioned reflex of Pavlov is a double reflex. In the first the receptor is at the periphery and the effector is the cerebrum, in the second the cerebrum acts as the receptor and the impulse passes through the reflex centers to bring about the final response in a peripheral effector. This theory of the central nervous system exalts the importance of the reflex centers. The theory is being tested at St. Andrews Clinical Institute, and is found to be of great value in the elucidation of the early symptoms of disease. It enables the drawing up of a rational classification of symptoms, and gives a clue to their relative importance.

1. Determination of the Basal Metabolism from the Carbon Dioxide Elimination.—John T. King, Jr., cites as advantages of using carbon dioxide elimination instead of oxygen consumption as an index to basal metabolism that (1) the apparatus needed to collect and weigh carbon dioxide is simple and stable. (2) The method is "open," thus preventing danger of possible respiratory infection for which the closed methods have been criticised. (3) By weighting the carbon dioxide output one needs to make no corrections for temperature and barometric pressure, such as becomes necessary in using volumetric methods of oxygen consumption. (4) The psychic effect upon the patient is favorable in that he may be assured that he is breathing fresh air and he is not subjected to the annoyance of the moving spirometer and buzzing fan, often a part of the closed apparatus. (5) Statistical studies upon protocols of two groups of experiments with the Atwater chamber calorimeter show a somewhat higher coefficient of correlation between carbon dioxide and measured calories than exists between oxygen and measured calories. (6) An analysis of 157 published observations upon gas exchange showed that carbon dioxide is either not "washed out" during the practical application of the basal metabolism test, or else it is "washed out" in negligible amounts. (7) Results of measurements of carbon dioxide obtained by the writer's method corresponded closely with those published by Bendict and his associates. (8) The practical application of the proposed method has been satisfactory in several hundred observations upon all types of patients. The method should not be used in diabetes because of the altered respiratory quotient in that disease. The apparatus employed consisted in the older United States Army gas mask, which was used to deliver outside air to the subject and to carry expired air to tubing leading to three jars, identical in construction to those which formed a part of the original Benedict "portable" apparatus. Resistance to the passage of air through the jars was measured by inserting a water manometer between the subject and the first jar. The writer concludes that carbon dioxide elimination seems to be at least as accurate and possibly a more accurate index to heat production than is oxygen consumption.

2. The Localization of Bacteria in the Upper Air Passages.—Arthur L. Bloomfield studied eight clinically healthy persons, in whom topographical cultures confirm his previous observations with reference to the normal flora. *Staphylococcus albus*, diphtheroids of various sorts, Gram-negative cocci, and variable transient organisms were widely and more or less uniformly distributed throughout the mouth and pharynx. The *Staphylococcus aureus* is not a normal inhabitant of the upper air passages. It was encountered under two conditions: (1) As a transient in nose or throat, and (2) associated with chronic focal infection. Beta hemolytic streptococci were found associated with acute tonsillitis or acute infections, such as influenza and scarlet fever, in chronically diseased tonsils, and occasionally as transients. The general bearings of these studies on the question of the mechanism of respiratory infection seem to the writer to be as follows: (1) Aside from the normal flora, bacteria do not as a rule grow free on the mucous surfaces of the upper air passages. (2) Special conditions are necessary to account for the presence of foreign organisms—either a local infection or a transient invasion.

3. The Ice-Box Modification of the Wassermann Test in the Diagnosis and Treatment of Syphilis.—Albert Keidel and Joseph Earle Moore have examined by the ice-box method 300 cases in parallel series with Wassermann tests performed according to the original technique. In performing the two series of tests identical "set-ups" were employed and the series were done with the same preparations on the same days, except that on account of the longer incubation in the ice-box the second incubation for completing these tests was performed the next day. Although the series was small for such a purpose, it has demonstrated to the writer's satisfaction an important superiority in its selection of uncured treated syphilitics. Although they favor its employment for diagnosis, they say they do so guardedly, and accept no positive results without careful scrutiny of all available data in the case.

Hunger Syndrome of Italian Prisoners in Germany.—Bolaffio writes at much length on this subject. Two German prison camps, at Rastadt and Halle, are specially considered. Generally speaking, there was a triad of symptoms—bradycardia, polyuria, and edema. The two first named were regarded as due possibly to some intoxicating substance acting alike on the myocardium and renal cells. The polyuria was regarded as due to the heightened accumulation of the water of catabolism. This hunger syndrome, according to the author, has no connection whatever with any avitaminosis. In the two camps, at least, no xerophthalmia developed which would seem to show that the fat soluble vitamine was not responsible by its absence; and, as a matter of fact, there was no evidence that any vitamine was absent from the diet despite the shortage of fats. Bradycardia in this syndrome might, of course, be regarded as akin to that of hibernation in animals and myxedema in mankind, in both of which conditions nutrition is notably slowed. It is very evident in professional fasts. Polyuria seems hard to explain unless we regard it merely as the result of a peculiar type of edema or hydremia in which nature endeavors to get rid of some of the retained water. An explanation of edema is still more difficult, and, as already stated, the action of some unknown substance directly on the function of the renal cell seems the most plausible.

Mortality in Italy.—During the triennium before the war the mortality of this country averaged 18.28 per 1000. In 1915 it rose to 19.53 (which figure does not include the earthquake victims). In 1916 it was 19.66, but in 1917 it fell slightly to 19.20. In 1918, including war victims, it mounted to 35.39, but without these the immense mortality of influenza would have added 12 deaths per 1000 to the normal. In 1919 the figure had dropped to 19.01, which may be regarded as only slightly above normal. If we add the victims of war and earthquake the death rate of 1915 was 22.28; that of 1916 23.32, and that of 1917 was 26.20. This figure, through the influenzal deaths, as stated above, increased in 1918 to a maximum of 35.39.—*Il Policlinico.*

Society Reports.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Forty-third Annual Congress, Held in Atlantic City, May 30-June 1, 1921.

THE PRESIDENT, DR. HARRIS P. MOSHER OF BOSTON, IN THE CHAIR.

(*Concluded from page 744.*)

Aspergillosis of the Maxillary Sinus.—Dr. Ross HALL SKILLERN of Philadelphia reported this case in a man about 50 years of age, who presented himself with vague symptoms referred to the left maxillary sinus. There was some unilateral apparently non-fetid nasal discharge, a feeling of fullness over the left antrum, vague head pains, entirely atypical of sinusitis. There were no periods of congestion or depression and no post-nasal discharge. At times there was cacosmia, but never marked. Examination revealed a slightly congested lateral nasal wall, but was otherwise normal. A needle puncture of the maxillary sinus was made. Considerable resistance was offered to the ingress of normal saline solution. Mindful of the fatalities reported by Gordon following needle puncture in which there was difficulty in forcing the irrigating fluid into the sinus, the irrigating fluid was injected with the utmost caution. Finally fluid returned from the nostril on that side. It appeared slightly turbid but no free pus was observed. After the injection of at least sixteen ounces, there appeared in the washings small white inspissated masses which resembled cottage cheese. Lavage was continued until the antrum was free, the injected fluid returning clear. The patient expressed himself as greatly relieved. He did not return for nearly a week when further needle puncture and lavage were negative; the patient was feeling quite well. He was to report should any of the old symptoms appear. Several months had elapsed and there was apparently no recurrence of the trouble. The pathological examination by Dr. Case showed that the specimen was small, soft, and possessed no characteristic appearance that might have suggested the diagnosis. As the specimen had been placed in formaldehyde solution a cultural study was impossible. Sections imbedded in paraffin, stained with hematolin and eosin and examined histologically under the microscope were found to contain a close myselial network with an occasional conidiaspore surmounted by a fanlike arrangement of conidiaspores. The hyphae took a faint pink stain but the fructifying bodies were yellowish in color, apparently resisting the penetration of the dye. The diagnosis was aspergillus, probably of the species *fumigatus*.

Dr. LEE MAIDMENT HURD of New York related the case of a woman, 50 years of age, who came to him for some obstruction of breathing. She had a deflected septum and the usual signs of chronic nasal catarrh. Transillumination showed the left antrum to be dark. He washed the antrum out. The fluid showed aspergillus with *B. pyocyaneus*. He washed the antrum with saline and injected it with silver. He then instituted intranasal drainage, but all with no effect. He tried many different antiseptics without effect. At length he inflated it every day with equal parts of boric acid and aristol, and within a week it cleared up.

A Case of Intranasal Ethmoid Exenteration Accompanied by Uncontrollable Hemorrhage. Death.—Dr. DUNBAR ROY of Atlanta, Ga., reported this case, which occurred in a male, 18 years of age, who had a supurating ethmoiditis with numerous polypi. He was operated upon on the left side with uneventful recovery. Four months later the right side was operated upon. Four days afterward there was hemorrhage from that side which was readily checked. Two days later a severe hemorrhage occurred from both sides for which the nose was tightly packed. Ten days later there was free bleeding from both nasal cavities. The blood always clotted freely. As the greatest bleeding seemed to be from the left side, the left common carotid artery was tied under anesthesia. Five days after this hemorrhage occurred from the neck incision, and again on the following day. It was decided to open the incision in the neck and tie the bleeding vessels. The patient took a few whiffs of gas and stopped breathing. No autopsy was allowed, but the incision in the neck was opened and all the neck muscles and fascia were undermined and an immense cavity was found filled with clotted blood. No blood examination was made as the blood clotted freely and it was expected that the hemorrhage would be controlled. Evidently a slow bacteremia had been progressing for some time, due to the absorption for years of pus from the ethmoid cells and this had undermined the coats of the blood vessels as well as the integrity of other body tissues. While the immediate cause of death was the general anesthetic, this would not have produced death had there not been such excessive loss of blood and the whole system in an abnormal state. This unfortunate termination emphasized the great danger of these extremely severe cases of ethmoiditis.

Neuralgias of the Trigeminal Tract and Facial Neuralgias of Other Origin; Impressions Derived from a Survey of 535 Cases.—Dr. CHARLES H. FRAZIER of Philadelphia read this paper. In order that there might be no misunderstanding as to what he implied he described the characteristic features of major trigeminal neuralgia, stating that it appeared suddenly and without any apparent exciting cause, and with few exceptions after middle life. A sharp, shooting, stabbing, lancinating pain was experienced first in one of the three divisions of the trigeminal nerve, usually the second or third. The distribution of the pain without variation was referred to the terminal distribution of the nerve involved to the lips, gums, tongue, teeth, nose, forehead. The attacks were of varying duration, a week or two at first, and two or three in a year, but as time went on they were of longer duration and greater frequency. The pain was not controlled by morphine. It would seem that peripheral infections, including sinus disease, played no part in the etiology. For a hundred years or more the etiology had been a matter of speculation and we were today as far as ever from any clear-cut conception or any convincing data as to the prevailing cause. There were other neuralgias of the trigeminal nerve that had a specific cause. In regard to the treatment of major trigeminal neuralgia, Dr. Frazier restricted his remarks chiefly to experience with the major operation. In the series of cases analyzed there had been 204 avulsions or sections of the sensory tract, five complete excisions of the ganglion, and five partial excisions of the ganglion. The major operation had long since been robbed of its terrors; the mortality once five per cent. had been reduced to less than one per cent. There had been but one operative fatality in the last 177 cases of this series. The vast majority of the patients expressed complete satisfaction with the results. At one time or another certain variations in the operation were introduced. For a while section of the root was substituted for avulsion but to no advantage. In a few instances he had left intact the inner fasciculus of the sensory root, when the ophthalmic division was not involved, in the hope that by so doing trophic keratitis might be avoided. He was now awaiting the results. Should there be any recurrences this modification would have to be abandoned. Latterly he had been able to conserve the motor root and thus prevent the atrophy of the temporal muscles which hitherto had interfered with a perfect cosmetic result. This modification made it possible to operate on both sides in bilateral cases. All the technical difficulties had been mastered and the operation was now one of the most satisfactory the neurosurgeon was called upon to perform.

Dr. GREENFIELD SLUDER of St. Louis, Mo., said that in the course of his paper Dr. Frazier spoke of the sinuses of the perinasal space as, in all probability, not being the cause of trigeminal neuralgia. He has seen three cases which he thought were such cases. Dr. Cushing in a paper last summer explained a case in which the pain was from the major neuralgia of the trigeminus. In conversation with the speaker he had expressed the opinion that these cases were all spilled over and he put in his text that there was no reason to assume that the second division of the fifth nerve was the origin of the pain, and that it was spilled over. It was difficult for him to understand how these cases could be spilled over from the trigeminus from his own experience and that of Dr. Cushing. He had a dozen

ophthalmoplegic migraines in which the sphenoid was operated upon with relief. To his mind these cases were explicable by virtue of thin bone, which separated not merely the optic nerves, but also the third, fourth, and sixth nerves. If these cases, then, were of sphenoidal origin, and explicable by the thin separation of the lining nerve trunks, they could readily recur for the same reason that established it in the beginning. Dr. Frazier spoke also of pain that was stopped by cocainization of the palatine or nasal ganglion. The fact of pain transmission then arose in his mind. The question of the sympathetic came in; and it seemed to him that as no other nerve connection was available, it must be assumed that the sympathetic became capable of afferent transmission. The literature on the subject of the possible sensory attributes of the sympathetic was very extensive.

Dr. Ross Faulkner of New York City stated that some years ago Dana, writing on tic douloureux, mentioned the fact that a case of two years' standing could be cured by castor oil. He thought there might be some truth in it and had tried it. To his surprise some of the patients were relieved of pain for quite a long time. The method employed was almost as severe as operation. He gave it every night. It was by all means worth trying. The etiology of this condition was very much of a mystery; he had never been able to get any light on the solution of it. The method he used for the injection of alcohol he had practised for a long time on the cadaver. By using a good deal of cocaine and a needle with an abrupt bevel to it, he was able to determine whether the point of the needle was in the nerve. He used three or four drops of cocaine for anesthesia. Not more than ten drops of alcohol was used for that sort of injection. He had six cases at least that had never come back. The majority came back within a year or even six months. In the second division of the nerve he had not had satisfactory results. One could not get into it but must put the alcohol around the nerve. In the third division one could work easily and get complete anesthesia with the injection of alcohol. The good results obtained with this method justified its being tried in all cases in the third division. All the cases should be treated with castor oil first; and if this failed alcohol should be injected into the nerve. With the first and second division of the nerve it was difficult to get a result unless one injected the ganglion. This he could not recommend because if the direction was not right, one might get into the cavernous sinus or the carotid artery.

Dr. Charles H. Frazier of Philadelphia, Pa., said he agreed with most that had been said in the course of the discussion. He took exception, however, to Dr. Sluder's reference to his remarks on a case of low-grade tic. In his opinion there was no such thing. A correct diagnosis of tic douloureux presupposed a violent, excruciating pain, a pain of great intensity and severity. With regard to tic douloureux, or major trigeminal neuralgia, there should be no conflict of opinion as to its recognition. It was quite distinct from sphenopalatine neuralgia to which the discussion had been chiefly devoted. That the latter might be of sympathetic origin was not unlikely. Alcoholic injection of the sphenopalatine ganglion for obvious reasons was not comparable to the injection of the gasserian ganglion or its divisions. In his address he had not touched upon the subject of alcohol injection because the subject was too big. In the management of patients he never urged one or the other method, but after laying the facts before the patient left the choice with him. In nine out of ten cases, if the patient had suffered for only a year or two, he would choose the injection; if for a longer time, and he had already had several injections, he elected operation. He did not agree with Dr. Faulkner as to the variations in the period of relief following injections of the second and third divisions, nor did he agree with him in his prohibitive attitude towards injection of the ganglion. In very old people, in the exceptional case in which there might be some contraindication to operation, when the ophthalmic division was involved, and in cases of inoperable carcinoma of the face, he had not hesitated to recommend and practise ganglion injections, and he had found these injections welcome.

Nasal Tuberculosis.—Dr. William B. Chamberlin of Cleveland, Ohio, presented this paper, in which he stated that nasal tuberculosis was rare, but the primary form not as rare as ordinarily supposed. There was still some confusion in the use of the terms lupus and tuberculosis. Zerinko's classification into proliferative and ulcerative types was probably simplest and best. He thought the term lupus should be dropped though Killian still clung to this term on account of the attenuated form of the infection and the chronicity of the involvement. The symptoms were usually those due to nasal obstruction with increased secretion. Pain was rare. Bleeding and crust formation were occasionally present. The places of predilection were usually the cartilaginous septum, inferior turbinate, nasal floor, and lateral nasal wall, in the order named. Bone involvement was secondary. Infection might be due to inhalation or to a direct lesion from an infected finger nail. The tubercle bacilli were always rare and might not be found at all. The presence of giant cells in fields of epithelial and lymph cells established the diagnosis, even though typical tubercles or tubercle bacilli were not found. Typical miliary tubercles with centers of cheesy degeneration were pathognomonic. The essayist brought out the differential points between lupus, syphilis, malignancy, and foreign body with granulation. The treatment was surgical removal, with subsequent application of lactic acid or superheated air.

Dr. Emil Mayer of New York said he was one of those who still felt that they should retain the term lupus, because there was a great deal of difference between tuberculosis and the attenuated form of tuberculosis that we called lupus. Why not consider finger-nail infection? These were cases in which the disease appeared in an area that could be reached easily by the finger-nail on entering the nose. There was another form of lupus that could not be classed with either the ulcerative or the tuberculous. There were lymph exudative forms. He had seen cases of tuberculosis of the nose in which the only symptom was repeated attacks of laryngeal spasm. Examination showed yellow exudate which eventually showed miliary tuberculosis. The importance of making a diagnosis between lupus and tuberculosis was that in case the patient had lupus you could assure him that he did not need a change of climate, and in the second place it relieved him of the fear of conveying contagion. Why not treat these cases with the galvanocautery? That could be done safely in the nose and the condition eradicated as thoroughly as anywhere else, and with less danger of having an open wound.

Dr. Lee Wallace Dean of Iowa City, Ia., stated that he had been making a study of chronic suppuration of the paranasal sinuses in patients suffering from pulmonary tuberculosis and also of chronic otorrhea in this class of patients. He found that many of the mastoids were tuberculous. To his surprise he found that tuberculosis of the paranasal sinuses was rare unless it was secondary to bone tuberculosis in the neighborhood of the diseased sinus. He had not found a single case of tuberculosis of the paranasal sinuses unless it was secondary to bone tuberculosis.

Dr. B. Alex Randell of Philadelphia mentioned a case of tuberculosis, which more or less completely involved the nasal chambers themselves. Many of the teeth were loosened. These were all removed and curettement of the alveolar processes carried out with removal of much of the nasal mucosa by Dr. Harrison Allen. The patient survived for twenty years or more.

Dr. Lee M. Hurd of New York reported several cases of mistaken diagnosis. One of these was a case of so-called lupus—lupus of the lip and vestibule. Sections were found by one pathologist to be tubercular. The case cleared up under mixed treatment. Other cases that were diagnosed as tuberculosis all cleared up under antisyphilitic treatment. They were all in the anterior part of the nose.

Dr. William B. Chamberlin of Cleveland, Ohio, said that personally he could not see any great justification for the term lupus. Dr. Mayer did not hear his remark about the finger-nails being the most probable cause of infection. Air-borne infection was the form most insisted upon, though the finger was the most probable cause of infection. His suggestion in regard to treatment was *à propos*. He thought one should be careful

in the use of the galvanocautery not to carry the cautery so deep that the cartilage became involved. In many cases he had made a probable diagnosis of tuberculosis, which was ultimately confirmed by the pathologist. In regard to Dr. Dean's reference to tuberculosis in sinus cases, he would say that he had not found it in such cases.

Some Observations on Localized Pulmonary Suppuration, Treated by Endobronchial Irrigation.—Dr. CHARLES J. IMPERATORI of New York contributed this paper, in which he said that lung abscesses might be divided into three classes: (1) Those caused by aspiration; (2) those caused by embolism, and (3) a type that was possibly tuberculous cavitation with a secreting lining of infecting organisms. Observations were conducted on seven cases, two being alive and still under treatment. Of the five deaths, one resulted from a carcinoma of the bronchus, in one a pneumectomy was performed elsewhere, the patient succumbing on the table, and three died from an intercurrent pneumonia. Of the five cases dying, four were autopsied and proven beyond doubt to be tuberculous. All of these cases were repeatedly examined and careful sputum analyses made; they were fluoroscoped and radiographed, and it was decided that they were probably not tuberculous. The remaining two cases had the same clinical characteristics as the other five. Simple bronchial irrigations in the control and treatment of lung abscesses of this type were of little use. It was possible that with the spiral irrigating tubes of Lynah better results might be obtained and this method pursued in subsequent cases. Various medicaments were used in some of the early treatment of these cases, all with negative results. Warm saline solution and the injection of olive oil, impregnated with five per cent. bismuth, seemed to be as efficacious as anything. Idiopathic lung abscess, by which was meant a type or abscess other than that directly traceable to aspiration of trauma of some foreign substance, or the embolic abscess following some surgical procedures was possibly a tuberculous cavitation with a lining area of pyogenic organisms. This was not given as a definite conclusion but was merely suggested as a result of personal observations and must be proven by a larger series of cases.

Dr. EMIL MAYER of New York said that anything that could be done for these patients was of such value that it should receive every bit of recognition possible. He called attention to the need of a certain amount of care in not making irrigations too frequently. These patients received, as a rule, a hypodermic injection of morphine and required a fairly strong solution of cocaine to render the bronchus as free from cough and irritation as possible. It must be borne in mind that while they had a dreadful disease with which to deal yet they had no right to inflict the cocaine habit on these poor individuals.

Dr. GEORGE H. RICHARDS of Fall River, Mass., asked what objection there was to making a direct opening into the lung, resecting one or two ribs, and establishing direct outward drainage. He related a case in which this procedure was employed. The patient continuously got well and was back at work at her occupation. Was there more risk from the surgical operation of making an opening directly into the lung?

Dr. HENRY L. SWAIN of New Haven, Conn., replying to Dr. Richard's question, said that an opening on the outside presupposed that one could readily discover where the abscess was and could get at it from the outside. He had met a few cases in which that was not easy, even after the injection of bismuth. The abscess could not always be located with any degree of safety or accuracy. Dr. Swain asked Dr. Imperatori how much trouble he had in getting his patients accustomed to the dosage. He spoke as though he always operated on the recumbent patient. He thought that if one could get the patient to sit up the injection would stay in better than when he was lying down.

Dr. WILLIAM B. CHAMBERLIN of Cleveland, Ohio, cited a case of his in which removing granulation tissue and plugging one branch proved beneficial. This boy, 18 years of age, gave a history of purulent expectoration since he was six years old, probably produced by a foreign body, though no evidence of it could be found. Subsequent to the injection, the purulent discharge decreased decidedly, and the odor almost entirely disappeared. There was marked improvement after such treatment, no bismuth being used.

Dr. R. B. CANFIELD of Ann Arbor, Mich., reported a case of pulmonary abscess similar to one described by Dr. Imperatori. It occurred in a child of 11 years who had a pulmonary abscess of two years standing of unknown etiology from which she expectorated about six ounces of foul pus at intervals of five or six days. Bronchoscopy, aspiration, and the use of compound tincture of benzoine secured a satisfactory recovery after several treatments. The satisfactory result of treatment was confirmed by the *x*-ray which showed a steady diminution in the size of the abscess and its ultimate obliteration.

Dr. CHARLES J. IMPERATORI of New York, in closing the discussion, said the point was whether he was correct in his assertion that these lung abscesses might be caused by any other means than by straight aspiration and embolism. Answering Dr. Mayer's question, the patient never got more than ¼ of a grain of morphine, measured in minims. Usually he got six or seven minims of magendie solution. The amount of cocaine was never more than a dram. The method of cocainization was with a Cohen applicator. The application was made to the base of the tongue and then to the cushion of the epiglottis. With an applicator syringe, at the same time, the larynx was touched and a drop of cocaine was injected. After waiting five minutes this was repeated. Then the trachea was sprayed with three or four sprays of a ten per cent. cocaine. Then as the bronchoscope was passed one application was made to the carina. In reply to questions that had been asked, Dr. Imperatori said that he knew of one case in which outside drainage was employed, and of several cases in which iodine and olive oil were used by the general surgeon. He always bronchoscoped the patient in the reclining position and usually employed a 7 mm. tube. He did not believe that the solution stayed in the bronchi, but the reason for injecting the saline solution was to soften and liquify the pus that one was not able to suck out with the aspiration appartus. Following Yankauer's technique he injected eight ounces and then sucked it out. Knowing that Dr. Lynah was injecting these abscesses and radiographing them, he had decided to use bismuth. At first he used bismuth subnitrate, but later changed to bismuth subcarbonate. He had never used iodine. In regard to the danger of hemorrhage in tuberculous cases, when working at the Riverside Hospital he had irrigated a number of lung abscesses with negative results. If any case showed a tendency to bleed he discontinued the use of the bronchoscope indefinitely.

Group Head Surgery.—Dr. B. B. SHURLY of Detroit, Mich., read this paper, in which he declared that if efficiency and humanitarianism were not sacrificed by greed, disloyalty, lack of harmony and cooperation, the group system was sure to win. The advantages to the patient were self-evident. He realized fully the necessity of laboratory, *x*-ray, dental examinations, and hospital observation at a fair fee. There was the danger in the group system of machine diagnosis and repair shop methods. Group head surgery must be affiliated with, or control a head hospital and teaching opportunities to be scientifically progressive and efficient. In their specialty at the beginning of the war, regular medical officers who were often without interest or training in the work, were assigned to duty as eye, ear, nose and throat specialists. The committee of this society had changed this. Group head surgical units were organized and successfully performed enormous labor in this country and abroad. The original estimate of 200 beds for head surgery in a 1000 bed hospital devoted to army hospital work was approximately correct. The advantages of group practice were better diagnosis and scientific work, cooperation, mutual interest, conservation of effort, quick service to the profession and the public, the division of labor, specialization along lines particularly interesting to the individual, the pleasure of working among the sick where no man thought he owned a case, cooperative system in buying instruments and general equipment, conservation of office space, the use of team work night or day, the practical value of an office and hospital together that could be operated by the same staff for the mutual advantage of the patient and the practitioner.

If state and industrial medicine with health insurance were to absorb private practice it would be necessary to adopt a feudal group system to protect the practitioner and the public who demanded private service. It would be of advantage in case State medicine and State hospitals increased to combine with other groups for personal protection and existence. The disadvantages of group practice were that the personal equation between the physician and the patient was lost, and machine and dispensary methods prevailed unless carefully guarded against. It was difficult to obtain a group of men who were temperamentally fitted to associate in harmonious endeavor. It was difficult to obtain men who did not overestimate their personal value and who entertained sufficiently broad and humanitarian views to handle patients properly.

Report of Cases of Cancer of the Esophagus, Treated by Radium.—Dr. D. C. GREENE of Boston made this presentation. He said it was remarkable that cancer in the esophagus was in the majority of cases well advanced before patients began to be troubled with difficulty in swallowing, and this accounted in part for the unsuccessful results in a curative way. Esophagoscopy had rendered the diagnosis of the site and nature of the lesion a relatively simple matter, but it was usually impossible to determine accurately its size and extent. The surface application of radium by means of bougies loaded with radium tubes had in his hands been productive of only discomfort and aggravation of symptoms without any beneficial results. This method was at best inaccurate and apt to cause burns of the normal epithelium on account of the dislodgement of the applicator from the original position in which it was placed. The technique of the method which he now employed was as follows: Under ether a medium-sized Mosher esophagoscope was passed down to the growth, the field cleared by suction, and a radium seed inserted into the most prominent portion of the growth to a depth of about a centimeter. The trocar for this purpose was of sufficient length to be passed through a seventeen inch esophagoscope, and sufficiently heavy and rigid to make possible the accurate placing and insertion of the point when the instrument was held at its proximal end. The usual dosage was about five millicuries in a single tube or distributed in two or three tubes. An element of danger that must be recognized in placing the tubes was the possibility of perforating the wall of the esophagus into the aorta or into a bronchus, which might result from an implantation too close to the outer wall. After citing a typical case, Dr. Greene said that in a general way it might be stated that patients could be given a moderate degree of relief for two or three months by this method. It had been possible to give this degree of palliation with relatively little discomfort from the treatment. Of eighteen cases treated by this method by the writer, fifteen were males and three were females. The tumor was located in the upper third of the esophagus in six, in the middle third in three, and in the lower third in nine. The youngest was 45 and the eldest 65 years of age, the average age being 57 years. The average duration of life after beginning treatment was three and a half months. Four patients were still under treatment. Only one of these was showing definite improvement in the local condition and in general health. Another who had been under treatment for five months was gaining weight, but the local process in the esophagus was still active. In nearly every instance the patient was able to swallow liquids up to the end and gastrostomy was advised only twice.

Report of a Case of Carcinoma of the Larynx, and One of Sarcoma of the Nasopharynx Treated with Radium.—Dr. JOHN R. WINSLOW of Baltimore, Md., reported these cases. He said the first was a male, 56 years of age, with a large lobulated intralaryngeal tumor without ulceration, apparently attached to the left arytcartilage with a tongue-like projection into the hypopharynx. Examination of a specimen showed the growth to be carcinoma. Preliminary tracheotomy was followed by seven hours of radiation, externally screened by three millimeters of lead, and held at a distance of one centimeter from the skin. This was followed by immediate dysphagia and a bad skin burn. In about two weeks all symptoms relative to breathing or swallowing had disappeared and within a month all trace of the growth had vanished. The second patient was that of a white boy, 19 years of age, with a voluminous tumor in the epipharynx. Examination of a specimen showed sarcoma. Tracheotomy with subsequent removal of the growth was followed by recurrence within two months. This was treated by radium partly by direct contact but mainly by needles inserted into the growth. Because of unavoidable interruptions treatment was extended over more than two years. The patient had now been free from symptoms of growth for about a year.

Radium Emanation: Its Advantages Over Radium for Use in the Upper Air Passages. A New Way of Applying It.—Dr. OTTO T. FREER of Chicago made this contribution, in which he stated that the treatment of malignant laryngeal disease with radium rays required a comparatively large dose of emanation, from 100 to 200 millicuries applied at each sitting, in order to reduce the time of raying to a minimum in the irritable laryngeal region and to flood the territory under treatment to its utmost pathological limits with rays sufficiently close together to destroy all microscopic carcinomatous implants. Small doses of radium could not do this. The writer's method of applying radium was as follows: The applicator was passed into the larynx with the aid of the laryngeal mirror as in ordinary swabbing of the larynx. The larynx was anesthetized with a five per cent. spray of cocaine followed by swabbing the interior of the larynx with pure cocaine flakes upon a moist swab. The clamp was then put on with the aid of an assistant. Anesthesine powder was then puffed into the pharynx and larynx. This itensified the action of the cocaine and quieted the retching caused at times by cocaine in certain throats. The applicator was now introduced, the screen being placed exactly upon the growth in the glottis, upper larynx or fossa pyriformis where it was wanted, while the assistant guided the vertical stem of the applicator into the open jaws of the clamp, which were closed when the screen was in the right place. The saliva pump was then started and the patient left in the assistant's care. Should retching occur anesthesine powder or a little cocaine spraying would usually stop it without removal of the applicator, but if it became violent the applicator was taken out, cocaine sprayed into the throat, and the applicator replaced. Some patients quietly endured the applicator for an hour or more; others needed it taken out once or twice during the hourly session. For nasal application a headband was used upon the forehead of which four small clamps were fastened. By proper bending of the wire stem the screen might be made to fit into any desired place in the nasal cavity, or pernasally, in the nasopharynx, where it was held in place by closing the clamp. Six laryngeal and four pharyngeal carcinomas were treated in this way. So far no patient had shown a local relapse, but in one the larynx had been invaded from without by rapidly growing glandular tumors. In the extrinsic cases the appearance of the larynx became normal in from four to eight weeks after the last treatment. In the intrinsic cases patients permitted the use of a large three or four case screen in the larynx as long as needed. In the worst of these cases, three weeks after the last of four intralaryngeal treatments of 100 millicurie hours each, the patient recovered his voice which had been hoarse for six months, and all trace of the carcinoma disappeared.

Radium in the Treatment of Laryngeal Carcinoma, with a Review of the Literature.—Dr. FIELDING O. LEWIS of Philadelphia, Pa., read this paper, in which he reported his experience in the treatment of sixteen cases of carcinoma of the larynx with radium since January, 1917. One patient in whom total laryngectomy had been performed, had a recurrence in the thyroid gland and died six months after operation. Another patient in whom a complete laryngectomy was performed two weeks ago had had large doses of radium within the larynx, and radium plaques applied externally for the past year. While the patient was doing nicely it was too early to record results. Another, in whom thyrotomy had been performed, with recurrence of the disease in the external wound, was treated with radium needles, and died eight months after thyrotomy. One with early involvement on the right side of the larynx was treated by radium needles

inserted directly into the growth, and early regression ensued. The patient was still living and there was no evidence of recurrence after four months. The remaining twelve cases which were considered inoperable were tracheotomized and treated vigorously by introducing needles into the growth and radium applied externally. In two cases there was marked regression of the growth, but after several months recurrence developed, and in spite of the use of radium, death occurred about a year after their first treatment. Out of 109 cases recorded in the literature, ten were living at the time the reports were published, showing a mortality of about 91 per cent. From reports Dr. Lewis was of the opinion that more recent improved technique in the use of radium, as practised at the Memorial Hospital in New York, offered more encouraging results. From his own experience, and from published reports, it would seem that radium was indicated only in the so called inoperable cases of carcinoma of the larynx, meaning those cases in which there was marked involvement of the cervical glands, epiglottis, base of the tongue, and the esophageal wall. Its analgesic effect in moderate doses constituted one of its most important benefits. It was valuable for those patients who refused operation. It perhaps exercised a beneficial effect in blocking the lymphatics before a radical operation upon the pharynx. Such brilliant results had been obtained in early intrinsic malignancy of the larynx by thyrotomy that in these cases radium should not be thought of except possibly as a postoperative measure. In the more advanced type of intrinsic cancer of the larynx, laryngectomy had prolonged the lives of many. Here again radium should not be considered a means of treatment except before or after operation.

Dr. HENRY L. SWAIN of New Haven, Conn., asked whether radium emanations should be used in laryngeal fibromyomata.

Dr. HENRY L. LYNAH of New York asked Dr. Freer whether he had made pathological sections of any of these cases.

Dr. NORVAL H. PIERCE of Chicago declared that without equivocation the last case that Dr. Freer reported was one of carcinoma. If this patient recovered his enthusiasm for radium treatment would be greatly increased.

Dr. CORNELIUS G. COAKLEY of New York stated that clinically he had seen similar lesions which had all the appearance of being carcinoma, and in these cases he felt that it was unwise to regard the condition as carcinoma. One should remove a section for examination, for it was surprising how often one might be mistaken.

Dr. ROBERT CLYDE LYNCH of New Orleans, La., asked what Dr. Freer thought necessary in order to screen the normal half of the larynx while exposing the diseased side.

Dr. HENRY L. SWAIN of New Haven, Conn., asked whether the flat container could be made to screen one side more than the other.

Dr. FREER of Chicago said that perhaps he had spoken a little too optimistically about sarcoma, but his experience had been that these growths yielded readily to radium, and this was confirmed by the literature. Most men spoke of nasal sarcoma as singularly good natured under radium treatment; they were better natured than sarcomata elsewhere. Even when Sir Felix Semon was writing about laryngology it was regarded as a dangerous thing to cut a piece off from a carcinoma in the larynx. When a thing appeared to be carcinoma he did not like to cut a piece out, unless he intended to take the whole thing away, larynx and all, if it proved to be such. If one intended to treat it with radium to cut into the growth might spoil one's purpose because the cells traveled fast. Regarding Dr. Coakley's thought that the cord was intact in one of the cases, he wished to say that he cut a piece out of the center of the cord with the elastic fibers; leaving the elastic fibers was a bad thing. The appearance of the growth and the symptoms justified him in considering it carcinoma. As to screening, they did not want to screen anything in the neighborhood of a carcinoma. The carcinoma was simply an evidence of widespread infection, and one wanted to reach all of it that he could.

Dr. D. BRYSON DELAVAN of New York expressed the belief that it would take a number of years to give us a definite established knowledge of radium treatment in these cases. Patience was the watchword in this matter. We could not tell much about it in a year or in five years. He had no doubt it would take ten years to establish very much regarding it. In the meanwhile it would be a good plan to hold our minds open and view judiciously the situation.

Dr. HARMON SMITH of New York stated that radium had more effect on sarcomata than on carcinomata, and particularly lymphosarcomata. Those in the nasopharynx yielded more quickly than did carcinomata in that region. As to the application of radium before or after operation, in view of the fact that radium shut off the channels by which the growth was disseminated, he thought it should be used before operation. A low order of carcinoma of the larynx that disappeared with the application of radium was likely to make one draw the wrong inference. Unless one had more definite evidence than the clinical observation, he could not determine the effect of radium on these growths.

Dr. CORNELIUS COAKLEY of New York expressed surprise that the method employed by the institute in New York was not more generally known. They used a pharyngeal tube of which the proximal end was just external to the lip. The distal end passed over the epiglottis and the arytenoid, and the whole pharynx was packed with gauze. This did just what Dr. Winslow's technique did, but it saved the patient from tracheotomy. The whole tube could be easily taken out at any time, if there was respiratory obstruction, but he had not seen that occur even during a long anesthesia when given in that way. The use of radium emanations was preferable to the use of radium salts. Dr. Coakley questioned the necessity of such an apparatus as that exhibited to them by Dr. Freer. He said Dr. Janeway had devised a method by which the radium could be kept in the larynx for two hours by simply cocainizing the larynx and using a suitable curved applicator.

Dr. HENRY L. SWAIN of New Haven, Conn., referred to an experience he had had with a case of apparent lymphosarcoma of the neck. The growth had originally been in the tonsils, and had been subjected to massive doses of radium within and *x*-ray without. An improvement had resulted and cure had apparently occurred. The man had since died of metastases in the abdominal glands, the liver, and the lung. The question came up whether the massive dose had anything to do with "driving the thing in," as the laity would put it, or whether the metastases started before the radium was applied. The latter was probably the solution, but we must consider whether the absorption of the products when so much living tissue was devitalized had anything to do with the future life of the patient. Dr. Coakley had objected to calling the growth which Dr. Freer had treated carcinoma. It really did not make so much difference what it was. It seemed to be carcinoma, was treated, and got well. Dr. Lewis spoke of making radium applications to the severe cases. He presumed he meant inoperable ones. He should prefer to hope that very early use of radium might cure the epithelial changes and render operation unnecessary.

Dr. ARTHUR W. WATSON of Philadelphia said he thought it might be of interest to the Association to know that the patient he had reported a few years ago as having been treated with radium, a case of carcinoma of the larynx, was still living and perfectly well. In regard to fibrosarcoma of the nasopharynx, it had seemed curious to him that in nearly all cases of fibroma of the nasopharynx that he had seen, and he had seen quite a number, the pathologist's report on a portion removed was sarcoma or fibrosarcoma.

Dr. JAMES A. LOGAN of Kansas City, Mo., expressed the opinion that Dr. Freer's method of applying radium emanations to the interior of the larynx was very interesting and instructive. Dr. Winslow's report of a case treated by extralaryngeal application of radium, in which a severe burn followed and a subsequent marked improvement resulted, might open the way for the external applications of radium or its equivalent; it was a method easy of application but much remained to be learned before they could determine what method

was best. Of course they had all removed nasal growth with the electrolytic needle and also by galvanocautery without recurrence, so he took it that they were at least progressing. Recurrences had been prevented by the use of radium in tumors in other parts of the body, suggesting that surgical interference in the first place should be followed by the use of radium, or, as suggested by Dr. Smith, they might use radium first, then surgery, and then radium.

Dr. Norval H. Pierce of Chicago said he rather antagonized the view that Dr. Coakley put forward in regard to always substantiating the laryngoscopic diagnosis of cancer of the larynx by microscopic examination. This was an old and much discussed question but he believed it was a dangerous formula to have such extensive credence among laryngologists. Whenever one could escape cutting into a carcinoma of the larynx he should do so.

Dr. Charles G. Coakley of New York stated that two or three times a year cases were referred to him for an opinion, in which other men, whose opinions he regarded as most valuable, had made a diagnosis of carcinoma of the larynx. He invariably in these cases removed a section if he was not frankly able to confirm that diagnosis. If one carried out Dr. Pierce's idea he could not put anything into the larynx, such as a swab, which was going to bruise it. He did not believe Dr. Freer had a technique by which he could remove the larynx without bruising it and squeezing the epithelial cells. Neither must one put radium in it for one was bruising the larynx by this procedure. He did not think it was wise to subject a patient to such a serious operation without being sure of one's diagnosis. No man should have a section taken unless he was willing to go on with the surgical means necessary in the case.

Dr. H. H. Forbes of New York said that if it was possible a section should be removed. One was then able to treat the case and to watch it. He had discarded entirely the so-called tubes or capsules in esophageal or laryngeal work, and was using the needles. It seemed to him that those who were using the emanations were getting better results than those who were using simply the needles. To avoid any possibility of infection they had a thoroughly aseptic method of preparing the patient, with alcohol and iodine used over the surface of the growth before using needles. However, he did not believe that infection was entirely the fault of their method of treatment. With regard to the question of screening, he felt that it had not been sufficiently emphasized that with an element as active as radium we should be guarded in exposing normal tissue to it as yet. He could not feel, in his own mind, that radium was going in to destroy simply the abnormal tissue, and not to destroy a certain amount of normal tissue also. He felt that the reaction was going to be on normal tissue as well. He felt, from the advanced cases that had come to them, among which they had had a number of deaths, that if he were to see those cases over again he would not expose them to the radium treatment.

Dr. Henry L. Lynah of New York said he thought there was a general misunderstanding about the question of biopsy. Sir Felix Semon said that if one had permission for immediate operation, biopsy was a safe procedure. He quite agreed with this statement. Reasoning clinically papilloma and many tumors of the larynx simulated cancer. In taking a specimen it should be taken from deep down and even part of the cord might be removed. The cord would regenerate when there was a mobile arytenoid joint and there was no danger of impairment of the voice. Regarding Dr. Greene's series of cases, Dr. Lynah said his experience had been similar to that of Dr. Greene and Dr. Forbes. All of those patients died. Two had sloughs which perforated the esophagus. Cancer did not seem to kill primarily, but the patients succumbed from secondary infection from septic food.

Dr. Robert Clyde Lynch of New Orleans, La., said he had had seven cases treated by the use of radium needles, of which four had died. He thought the patients were made more uncomfortable by the treatment and died sooner than they otherwise would have. Dr. Smith had spoken of a case in which he did a laryngectomy after an application of radium. The cuts showed what looked like cartilaginous tissue; there was tremendous sloughing of the parts, and the man died from the sloughing process. If operation was decided upon, the time for the application of radium was after the operation rather than before, on that account, Dr. Lynch asked Dr. Greene whether the radium seeds that he used contained four hundred millicuries of radium. Dr. Freer's results were so different from those he had been able to see in the cases of the men who were using radium in his section of the country, and from reports from other sections, that he wondered whether the difference in the content of the element used accounted for the difference in the results. In their part of the country they were disposed to be rather pessimistic about the result obtained in carcinoma of the mouth, pharynx, and upper esophagus when treated by radium.

Dr. D. Crosby Greene of Boston called attention to the fact that in his paper he did not claim to have cured any patients but that they had been relieved. With seed implantation one got necrosis of the part of the tumor which presented in the lumen. The patients stated that they were more comfortable and swallowed better. The end results, however, had been bad in all but one case. Nevertheless the method gave some promise of accomplishing more, particularly if combined with the use of Dr. Duane's new *x*-ray apparatus. They had had some good results with radiation. He expected to show next week in Boston two cases of apparent cure of cancer of the larynx by radiation. Their results with the surface application of radium to the larynx had not been as successful as Dr. Freer's, and he wished to pay tribute to Dr. Freer's ingenuity and skill in administering radium in this way. Almost invariably there was a certain amount of reaction following the application of radium in the larynx; so much so that he did a tracheotomy beforehand. At any rate he thought this did good in itself and avoided the danger of acute stenosis of the larynx.

Dr. John R. Winslow of Baltimore stated that the important point in these cases was the diagnosis, and for this they were rather dependent upon the pathologist. The laryngeal cases that he reported could have been treated by any method. It happened that at that time the more recent methods of applying radium were not known. The skin burn was due to inexperience. It seemed to him that Dr. Freer's doses were enormous.

Dr. Fielding O. Lewis of Philadelphia stated that in reference to the length of time the patients were able to retain these applications in the larynx, he might say that they used preliminary tracheotomy because they found that the reaction was so severe that this procedure had to be resorted to later; there was also an added advantage in putting the larynx at rest. Dr. Swain said he would prefer to use radium in the earlier cases of carcinoma of the larynx. He felt differently, because among the cases treated by radium so few were cured, whereas with thyrotomy 75 or 80 per cent. of cures were obtained when the cases were seen early. Regarding biopsy, he felt that there were borderline cases in which it was necessary to remove a specimen.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Die Heilbedingungen für die Tuberkulose im Hochgebirgsklima. By Dr. med. Bernhard Kurt Voigt. 70 pages with tables. Price, 15 Marks. Published by Johann A. Barth, Leipzig.

Jahresbericht der Gesellschaft für Natur- und Heilkunde in Dresden, Oktober, 1919, bis Mai, 1920. Published by J. F. Lehmann, Munich, 1921.

Within the Atom. By John Mills. 215 pages illustrated. Price, $2.00. Published by D. Van Nostrand Company, New York.

The Microtomist's Vade-Mecum. By Arthur B. Lee. 594 pages with figures. Price $6.50. Published by P. Blakiston's Son & Co., Philadelphia.

Medical History.

HOBART COLLEGE AND THE MEDICAL PROFESSION.

By BRANDRETH SYMONDS, M.A., M.D., LL.D.,
NEW YORK.

HOBART COLLEGE in Geneva, New York, has been closely identified with the medical profession from its foundation. It received a provisional charter in 1822. Three years later, when it had complied with all requirements, the regents of the University of the State of New York granted Geneva College, as it was then called, a full charter which gave to the College the right to confer all the degrees and diplomas which any university or college in Europe was privileged to grant, and the first class was graduated in 1826. In the same year there was a magnificent medical row in New York City. A circular dated August 1, 1826, says, "The late Professors of the College of Physicians and Surgeons, having seen fit to withdraw from the Institution without thereby intending to relinquish their accustomed functions, have organized another medical college, in which all but two of the former faculty take part," etc. This circular was signed by those medical giants, David Hosack, M.D., F.R.S., Samuel L. Mitchell, M.D., LL.D., Valentine Mott, M.D., John W. Francis, M.D., Wm. James McNeven, M.D., John D. Godman, M.D. These gentlemen "were appointed by the Trustees of Rutger's (formerly Queens) College, New Brunswick, New Jersey, the Medical Faculty of that Institution." Evidently the doctrine of State's rights prevented a continuation of this connection, for after the first year it was dissolved and in 1827 a "union was formed between these gentlemen and the trustees of Geneva College in the State of New York, by which they were recognized as the Medical Faculty of that Institution." Two leading lawyers, Thomas Addis Emmet and Josiah Ogden Hoffman, stated that "we have deliberately examined the charter of Geneva College and the act relating to the different colleges in this State and have no hesitation in saying that diplomas granted by Geneva College to those who shall study medicine with Rutgers Medical Faculty of that College are good, effectual, and valid to every purpose for which a medical degree is legally requisite, and equally so as that of any Medical College in this State." This opinion was endorsed by Chancellor Kent, but the question had to be tested in the courts, for the College of Physicians and Surgeons of New York City was intensly jealous of this new Medical Faculty. The P. & S. had absorbed the Medical Department of Columbia College in 1813, and its only competitor in the State was the College of Physicians and Surgeons of the Western District, located at Fairfield, which terminated its career in 1840.

The Rutgers Medical Faculty of Geneva College was a real rival, however, which thrived at the expense of the P. & S. in New York City. Its professors were better known, stronger, and more popular, the medical students more numerous and the graduating classes larger. So in 1830 the P. & S. got a kindly judge in the Supreme Court, who probably had gout and dreaded to lose his colchicum, to decide that Geneva College had no right to establish a Medical Faculty away from Geneva. To one who has seen Cornell University do the same thing in New York City and Union University in Albany, it seems ridiculous, but it served its purpose then. A circular dated November 1, 1830, says: "The undersigned, late Professors in the Rutgers Medical Faculty of Geneva College, New York, in answer to numerous inquiries, both epistolary and verbal, announce that they have resolved to suspend, for the present, the exercise of their collegiate duties as professors in the different departments of medical science. Unwilling to contravene the laws of the State, or the decision of its courts, which have recently declared that Geneva College does not possess the power of establishing a Medical Faculty in the City of New York, they address themselves to the unbiassed and uninfluenced opinions of their countrymen. Most of their Board have, for more than twenty years, others for a longer period, devoted their time and talents to the improvement of youth in the noble and important science of medicine; they trust with uniform and unequivocal approbation; with necessary and consequent improvement of the profession, and benefit to the cause of humanity. A medical institution had been reared by their hands from the humblest beginning into successful rivalship with the oldest and most prosperous university in the country; but when by years of vigorous diligence, and well-directed exertions, their situation excited the cupidity of those to whom, unfortunately, its government was confided, they relinquished their situations after the highest authorities in the State had not only acquitted them of all censure, but had passed a distinct vote of approbation in their favor. On abandoning their seats, they founded and erected on their own individual responsibility a New College; desirous of continuing their efforts in a cause in which they had been so successful; and from this institution they have for several years past sent forth numerous well-educated youth, who had repaired hither from different and remote sections of the Union. Let it suffice, that more than two thousand pupils have been educated under their care and direction during their entire collegiate labors. But the authorities of the State which, right or wrong, they are bound to obey, having seen proper to deny their protection, in order to sustain a monopoly and to prevent by legislative enactment, that competition so necessary to the free development of talent, they now withdraw from the task of official and public instruction; wishing to those who come after them all the success they may merit, unimpeded by those envious arts which may interfere with their usefulness." So this dream of Hosack, Francis, Mott, and the other medical giants came to an end.

Hobart College, however, determined to develop again its association with the medical profession, and there seemed great need for it. The little medical school at Fairfield, near Utica, was flickering out, and in fact came to an end in 1840, thus leaving the P. & S. the only medical faculty in the State. Western New York, on the other hand, was developing fast. The Erie Canal, which had been opened in 1825, was the great artery of transportation from the Atlantic seaboard to the Great Lakes. A branch of it ran down to Geneva at the foot of Seneca Lake.

and brought great prosperity to the entire region of the finger-lakes.

In 1834 a faculty of medicine was organized to hold its sessions at Geneva. It was a strong set of medical men and included Willard Parker, who died in 1884, leaving behind him a splendid record of great achievements; Thomas Spencer, who was Dean of the Faculty and had been President of the New York State Medical Society in 1832; Charles Broadhead Coventry, who was President of the New York State Medical Society in 1854. In March 1835, they persuaded the Legislature to amend the "General Regulations concerning the practice of Physic and Surgery" in this State, so that the diplomas granted by the Medical Faculty of Geneva College "shall have the same force and effect as licenses to practice Physic and Surgery as are given by law to the licences granted by any incorporated Medical Society in this State."

No opposition was raised to this amendment and the up-state legislators apparently passed one over the city members. At that time there were no real restrictions on the practice of medicine and surgery. No permit was needed, and no medical diploma was required until 1880. The back country was filled with irregular and unlicenced practitioners of all sorts, who had had no medical education. It was a slow and expensive trip to reach New York or even the Berkshire Medical College in Pittsfield, Massachusetts, for the only means of through travel as far as Albany was the Erie Canal.

Hobart thought that the amendment above mentioned carried with it all the privileges which pertained to an incorporated medical college. So the Geneva Medical College promptly sent a delegate to the next meeting of the State Medical Society. He was refused admission and immediately brought suit for a mandamus. Again a Justice of the Supreme Court of the State felt kindly towards the P. & S. and ruled that the amendment did not carry this privilege, though it gave every other right. In spite of this, Hobart's Medical Faculty flourished. A careful record of the graduates has been kept by Hobart College, but the students who attended the lectures are shown only in a few circulars of occasional years which the Librarian of the New York Academy of Medicine has preserved. The following table shows the gleanings of this information:

Year of Graduation	Graduates	Enrolled Students
1840	20	87
1841	37	119
1843	37	165
1845	44	183
1848	27	114
1849	32	106
Total	197	774

This table shows that only one-quarter of the class was graduated each year. As each student was required to attend lectures for two years, and only a few attended three courses, it is fair to assume that nearly one-half the candidates for the degree of M.D. failed to pass. This fact demonstrates the high standard required by the Medical Department of Hobart College.

In 1845 there was some agitation for an improvement in medical standards throughout the United States. The *New York Journal of Medicine* said in an editorial in May, 1846: "If there is to be any change, the different Colleges might do as Geneva College has done—make their examinations public, invite the censors of the State Society to be present, appoint a Board of Medical Curators who may also be present, and let a majority of votes of all be necessary to confer the degree of M.D. This plan has worked admirably at Geneva College and given satisfaction to the profession universally. Why may it not be extended to other institutions?"

Although it was not allowed to send an official delegate to the New York State Medical Society, most of its graduates joined that organization and several of them were elected president. Both its faculty and its alumni association were officially represented at the preliminary National Medical Convention which assembled at New York in 1846. Its delegates were also present at the meeting in Philadelphia which on May 7, 1847, voted "to resolve itself into the American Medical Association." From that time it was regularly represented at the meetings of the A. M. A.

In 1847 it took the epochal step of admitting to its lectures Elizabeth Blackwell, to whom it granted the degree of M.D. in 1849. She was the first woman to receive this degree in America. Her application to attend lectures was refused by all the medical colleges along the Atlantic Coast, and even at Hobart the medical faculty deemed it wise to submit the request to the students. Their reply was as follows:

At a meeting of the entire medical class of Geneva Medical College, held this day, October 20, 1847, the following resolutions were unanimously adopted:

1. Resolved, That one of the radical principles of a republican government is the universal education of both sexes; that to every branch of scientific education the door should be open equally to all; that the application of Elizabeth Blackwell to become a member of our class meets our entire approbation; and in extending our unanimous invitation we pledge ourselves that no conduct of ours shall cause her to regret her attendance at this institution.

2. Resolved, That a copy of these proceedings be signed by the chairman and transmitted to Elizabeth Blackwell.

She reached Geneva on November 6, after two and a half days of hard continuous travel from Philadelphia. On the 9th she wrote to a sister and after describing the nostalgia which she had for the first two days, she says:

This evening, however, I have finished my second day's lectures; the weather is still gloomy but I feel sunshiny and happy, strongly encouraged, with a grand future before me, and all owing to a fat little fairy in the shape of the Professor of Anatomy. This morning, on repairing to the college, I was introduced to Dr. Webster, the Professor of Anatomy, a little plump man, blunt in manner and very voluble. . . . He asked me what branches I had studied. I told him all but surgery. "Well," said Dr. Lee, "do you mean to practise surgery?" "Why, of course, she does," broke in Dr. Webster. "Think of the cases of femoral hernia; only think what a well-educated woman would do in a city like New York. Why, my dear sir, she'd have her hands full in no time; her success would be immense. Yes, yes, you'll go through the course, and get your diploma, with great éclat too; we'll give you the opportunities. You'll make a stir, I can tell you."

Judging from his addresses and general reputation, he seems to have been very broad-minded with an excellent knowledge of anatomy and a first-rate capacity for demonstrating on the cadaver. In her autobiography she says:

The behavior of the medical class during the two

years that I was with them was admirable. It was that of true Christian gentlemen. I learned later that some of them had been inclined to think my application for admission a hoax, perpetrated at their expense by a rival college. But when the bona-fide student actually appeared they gave her a manly welcome and fulfilled to the letter the promise contained in their invitation.

She spent another winter at Geneva and then received her diploma, as the leader of the class. Within a few years other medical colleges in different parts of the United States were conferring the degree of M.D. on women but the Medical Department of Hobart College was the pioneer in this movement and by its bold progressive action, overcame one of the impediments to woman's usefulness. 1921 is the centenary of her birth.

In 1852 the name of Geneva College was changed to Hobart Free College and this was further modified in 1860 to Hobart College. In the late sixties clinical instruction in hospital and dispensary was recognized as an important factor in medical education. Physical diagnosis demanded and anesthesia permitted the use of abundant living material for the students to observe and investigate. Geneva was a small town and could not furnish this. Some country medical schools maintained an existence in spite of such deficiency but the Medical Department of Hobart College did not feel that it was proper or wise to send forth its graduates without suitable clinical training. Unless it could give a medical education as good as any medical school in the land, it would not grant a diploma to a man only partially trained. So in 1872, the Medical Department of Hobart College, after nearly fifty years of fine needful work, graduated its last class. During that time it conferred the diploma of Doctor in Medicine on more than 700 graduates. More than four times that number received instruction there, if the students of each year are counted separately. The standard of qualification was high, as good probably as that of any medical school in the land. But when, owing to changing conditions, it could no longer give the best, it ended its activities in medicine. A year or two later the cabinets, equipment, etc., were sold to the Medical Department of Syracuse University.

Although Hobart terminated then its direct instruction in medicine, it never ceased to have a marked interest in the profession. Many of its graduates and students entered the medical ranks, especially as the demand for a preliminary education developed among the better medical schools. These began to require two or three years of college education and extended their new course to four years. A man had to spend six or seven years at College, undergraduate and medical, before becoming an M. D. and then he failed to receive his baccalaureate degree. Large universities could and did make arrangements by which the courses for the baccalaureate degree and that for the M.D. were so combined that both degrees were given after six or seven years of study. The small colleges where the highest humanities are taught, were unable to accomplish this, causing a great loss of character to our profession. So in 1906, Hobart College adopted the following provision:

Combined Degrees: Students who propose to study medicine in a reputable medical school that requires at least two years of college work for admission, may obtain both degrees, the bachelor's and the doctor's, in seven years, the time required for both degrees in other professions. The student who desires to avail himself of this privilege may proceed to the medical school when he has completed three years' work, including all that is specifically prescribed for the degree he seeks. When he presents to the registrar a certificate showing that he has finished one year's work in the medical school, he will be recommended for the baccalaureate degree.

A number of Hobart students have since used this privilege with benefit to themselves and our profession. How well it is regarded by the teaching faculty of medicine is best shown by the following letter from the Dean Emeritus of the College of Physicians and Surgeons of New York, the Medical Department of Columbia University.

Kennebago Lake House, Kennebago Lake, Maine.
June 9, 1921.

To Brandreth Symonds, M. D.

Yours of the 6th has followed me to the Maine woods, where I am fishing for trout and catching a rest and some fish.

I am pleased to testify to the broad and catholic spirit of the authorities of Hobart College which was shown some fifteen or so years ago in connection with the combined course in medical education. Columbia in 1890 instituted the combined course in recognition first of the cultural and liberal value of the work in the scientific foundations of medicine as required of medical students, and second, of the economic necessity of saving time for young men who were earnest and capable beyond the average requirement of collegiate standards. The combined course was therefore safeguarded against abuse by the requirement of a high standard and when applied both to medicine and to law, it marked an epoch making advance in professional education.

Hobart College was one of the first to extend the application of the principles involved in the idea of the combined course to its students and recognizing the opportunity for service, Hobart has permitted members of its senior class to attend first class medical colleges as students in medicine and has given credit for the one years' work in physiology, anatomy and biological chemistry, towards the baccalaureate degree of Hobart College.

The students who have availed themselves of this privilege have justified this action of the faculty of Hobart in helping to establish a new principle in education that work done *in absentia* can properly be credited by one college on the certification from another of equal standing.

A considerable number of institutions in New York and in other States have followed the lead of Hobart and the new principle is firmly established today. But when this action was taken first, it required courage, breadth of vision and confidence in the future of medical education.

It gives me great pleasure to testify that Hobart College was in the van with the leaders of progressive education. Faithfully yours,

(Signed) SAMUEL W. LAMBERT.

Dr. Lambert was Dean from 1904 to 1919 and since that time has been Dean Emeritus. Columbia University in 1921 conferred on him the degree of D. Sc., causa honoris.

As always, when the medical profession is concerned, Hobart College is the pioneer. And to-day Hobart College offers the very finest education preliminary to the study of medicine. The man or woman who treats the ailments, physical and mental, of human beings needs more than a purely scientific training. (Hereafter when the masculine pronoun is used, it can generally be understood to refer to both sexes, for our language is deficient in this respect. Hobart College has a splendid woman's department, The William Smith College, which is

under the control of the same administration and faculty, and is operated as a coordinate institution. It is not coeducational in the strict sense, for the two sets of students do not mix in the classes.) He needs a knowledge of human nature which is not obtained from dissection, the microscope, or the test-tube. The foundation of this knowledge is best laid in the study of the great intellects of all times and all countries for—"The paths we now tread o'er, Our fathers trod five thousand years before." The norm of human nature changes very little from age to age, and even its morbid symptoms seem to be modified almost none. Our instruments of precision enable us to make more accurate diagnoses and descriptions, but influenza dates back to the Dark Ages, at least, and bubonic plague attacked the Philistines in the days of Samuel. Such an education is found in an institution when the requirements for entrance and the under-class years include a goodly proportion of Greek, Latin and mathematics. Or perhaps a study of the best minds of the modern languages may be substituted for the Greek and Latin, and in both cases a plenteous supply of the finest writers of our own language is added.

The student is taught these expressions of the highest type of normal human nature by the professors themselves; men who are almost indissolubly linked up with the future of the college and of these students. They are not taught by instructors, recently graduated, whose desire in life is to become assistant professors elsewhere. The professors at Hobart are underpaid, as they are everywhere, but they have always had the strongest attachment to the College, for they realize the splendid opportunity there of coming into immediate contact with young human nature at its most absorptive age. Theirs is the joy of watching it unfold and begin to blossom, but just think of what it means to the youngsters. These are shown by precept and example what every man and woman ought to do, and what is forbidden. In the growth of civilization, personal restraint and inhibitions have been wrought into the fibre of human nature more and more. Some of these restraints are set forth concisely in the Ten Commandments of the Jews but the highest examples are the statements of our Lord—"Thou shalt love the Lord thy God with all thy heart and with all thy soul and with all thy mind. This is the first and great Commandment and the second is like unto it: Thou shalt love thy neighbor as thyself." Think of the repression of self, of the restraint and inhibition that are contained in these few words. It was far beyond human attainment when it was uttered, and even to-day human nature falls shockingly short of it. But it is the goal of Christian endeavor and at Hobart College, founded by a Christian gentleman, Bishop John Henry Hobart, it is woven into the curriculum.

Every department of science too receives proper attention in the course of study. After four years work at Hobart, or even three years, if he is bright and a hard worker, a man is properly trained to begin the study of medicine. During that time he has lived amidst the best hygienic surroundings for there is no more healthy country than the region of the fingerlakes of New York. The college is situated at the north end of the greatest of these, Seneca Lake. The mortality of its graduates, taken from the last general catalogue, is only 85 per cent. of the deaths expected by the American Table. The class of '81 shows an extraordinary record. Its thirteen graduates sat down to their Senior class dinner in June, 1881, and forty years later, at this writing, all are alive.

Somebody will say—in fact, it has already been said—that the education described above is a splendid foundation for every profession and business. Quite true but this appeal is to the medical profession, for it comes in contact with sick, suffering human beings and for them the highest humanity is needed. And such has always been taught at Hobart College.

1 West Ninety-fourth Street.

Origin of Clinical Teaching in Italy.—Professor Fedeli of Pisa recently published an article on this subject in the *Medical Clinic of the University*, an abstract of which appears in *La Riforma Medica* for July 9, 1921, xxxvii, 28. It has commonly been believed that priority in this respect belongs to France. He shows, however, that the original clinic was held at Padua in the year 1543. The clinician was Giovan Battista da Monte, who conducted a "school for practical instruction" in the S. Francesco Hospital up to the time of his death. This school did not survive its founder and it was not until 1764 that the first official medical clinic was established in Venice. This was followed before the year was out by the establishment of clinical instruction at the University of Pavia, with Borsieri as first incumbent. The latter was succeeded by the Frenchman Tissot and he in turn by the celebrated Austrian Peter Franck. The next clinic chronologically was established jointly at Pisa and Florence, making use of S. Maria Nuova Hospital in the latter city, while the teachers were from the University of Pisa. Bicchiere, the Pisan professor, demonstrated one case weekly in the Florentine Hospital. In 1781 the Medical Clinic of the Maria Nuova Hospital was formally opened, with 20 beds, 10 for each sex. One lecture was given daily at the bedside of the patient. Through the instrumentality of the Grand Duke several beds for teaching were established in the S. Chiara Hospital at Pisa in 1783 with Professor Torregiano in charge; and in 1786 this clinic was made officially a part of the University. Next in succession comes Geneva (1789), Bologne at the end of the century and Rome in 1815.

The order of establishment of medical clinics outside of Italy is given by Fedeli as follows: In 1714 Boerhaave established the clinic at Leyden and held two clinics weekly. This is usually stated to be the first official clinical chair, and with the exception of Padua in 1543 (and perhaps Oxford), has a safe lead over all others, the original clinic at Pisa having been unofficial. In 1745 Van Swieten established the first medical clinic at Vienna, following the lead of his master Boerhaave. In 1781 Prague followed suit, while the original German clinic was established in Göttingen by Peter Franck in 1786. Hufeland followed at Jena in 1793. There is said to have been clinical teaching at Oxford in 1680 and at Edinburgh in 1745, but no details are given.

RADIUM THERAPY IN CANCER.*

By GEORGE STUART WILLIS, M.D.,

NEW YORK.

VISITING PHYSICIAN AND DIRECTOR OF THE RADIUM DEPARTMENT OF THE NEW YORK POST-GRADUATE HOSPITAL.

THE use of radium in cancer is greatly on the increase. Much progress is being made in its application and the utilization of its rays, but the therapy is still very much in its infancy.

The progress of radium therapy has been slow for two particular reasons—first, the high cost of radium, and secondly, the lack of co-operation on the part of the medical profession in general. Unfortunately, the high cost of radium and of maintaining a department has been such that large institutions have found it difficult to finance. At the present time, very few hospitals throughout the country have equipment and enough radium for use in all branches of medicine and surgery, therefore its value in cancer has not yet been accurately determined.

We have now but few workers who are devoting their entire efforts to the development of radium therapy and we also find but few institutions that are endeavoring to standardize by the same method of treatment.

As for proper cooperation, it was unfortunate that when radium was first used in medicine it was boomed as a cure for all cancers. This unquestionably accounts for a great deal of the prejudice which still exists against its use, and I feel that even the most enthusiastic users of radium to-day have little hope that it will ever prove a cure for all cancers. That in the cure of initial and accessible growths radium will in the future show permanent cures, I feel confident; on the contrary, a growth that has progressed for any given length of time and has shown any evidence of metastasis must be considered only from the standpoint of prolongation of life. Even to-day, cooperation with radium therapeutists is lacking and very few men show the spirit that is absolutely necessary to develop the therapy. Surgeons will send hopeless cases expecting results from the use of radium, although they may have operated and reoperated upon the patient; and the profession in general seems loth to send malignant growths for anteoperative treatment. Personally I believe that all malignant growths and surrounding tissues should be thoroughly radiated before any surgical measures are performed. To bring this about it is necessary for the surgeon as well as the internist to have a more workable knowledge of the physics of radium and the action of the radiations upon normal and abnormal cells.

It is evident that the position of the radium therapeutist should be that of a consultant, and, as it is an accepted fact that a radium toxemia exists during the disintegration of a malignant growth, the entire supervision of the case should also be under his care. The radium therapeutist, however, cannot possibly be specially trained in all branches of medicine and surgery, therefore the application of the radium should be under the care of a specialist from each department who has been adequately trained. It is evident that proper cooperation by this method would tend to prove the true value of radium therapy.

Time will not permit of full discussion of the physics of radium and in passing I shall merely speak of the present controversy which exists between the radium therapist who is working with emanations alone and the therapeutist using radium salt itself.

Radium is constantly in a state of atomic disintegration and a gas known as the emanation is the result. All the therapeutic values of radium are a result of the disintegration of the emanation. This gas is in a constant state of formation and it has a life of approximately thirty days. To obtain the emanation various forms of mercury vacuum pumps are in use. The gas is pumped from a radium bromide solution and compressed into small capsules and, after measurement, is ready for use. A number of hospitals are using this method and the chief advantage is that the radium is constantly in a safe place and in no danger of theft.

As regards the use of the radium salt itself, it is packed in small glass tubes or put in metal needles for use in various growths. The result of the controversy narrows to a point of which has the better therapeutic value, the beta and gamma rays together or the gamma ray alone. It must be remembered that the beta ray has an absorptive value of only a centimeter of tissue, while the gamma ray has a decreasing value with each centimeter distance but a combined range up to ten centimeters of tissue. The beta rays are of many ranges of penetration, are very active and irritating in their action, and in number are at least nine times as numerous as the gamma ray, so that when gamma rays are used alone it is necessary to expose at least nine times as long.

The action of the gamma ray upon cell life is most ably summed up by Ewing: "Within three

*Read before the Alumni Association of the University of Buffalo, June 4, 1921.

to five days after the application in the cervical canal of 300 mc. of radium emanation in a platinum tube, there is hyperemia of the tissues, beginning exudation of lymphocytes and polymorphonuclear leucocytes, and swelling of all the cells. In the second week, the cords of the tumor cells present a characteristic appearance. The nuclei are swollen, homogenous, and hyperchromatic, the cells loosened, and fusion giant cells form. In the third week, the number of cells are greatly reduced. Many appear to suffer necrosis; others are invaded and mechanically broken up or compressed by lymphocytes. From the fourth to the fifth weeks, only nuclear fragments or an occasional giant cell are visible, or no traces whatever remain. Meantime, the stroma has been active and appears to take an important part in the process. Leucocytes become over abundant, the capillaries proliferate actively, and the stroma is transformed into granulation tissue in which numerous new capillaries penetrate and excavate the tumor cell nests. The gathering of leucocytes, lymphocytes, plasma cells, and polyblasts in the later stages of radium reaction may be extremely profuse, and in this respect the reaction is somewhat specific. Eventually the site of the tumor is occupied by granulative tissue from which slight serous and cellular exudate is discharged. Later, epithelium grows over the denuded surface, completing the repair. All manner of variations occur in the reaction of tumor tissue to radium. Complete simple necrosis follows over action of radium. Bulky tumors may present large areas of simple necrosis in which cysts form by liquefaction. The stroma as well as the tissue is destroyed, in which event extensive scarring will result."

In the foregoing scheme of changes it would appear that just enough radium had been employed to cause slow degeneration of tumor cells and stimulate regenerative growth of granulation tissue.

The American Radium Society in its endeavor to standardize the use of radium has adopted a classification of cases—A, operable; B, borderline or doubtfully operable; C, inoperable, D, advanced and hopeless; E, recurrences.

To classify our cases and also as an aid to prognosis it is necessary that a patient at first have a thorough physical examination; secondly, a complete uranalysis, and if the specific gravity is low or if albumin or casts are present a phenolsulphonephthalein test and a chemical blood examination; thirdly, a complete blood examination consisting of counts—red, white, hemoglobin and differential, and a pathological specimen to be taken for a laboratory report.

Treatment.—Much may be expected from the medical treatment of malignancies in conjunction with radium therapy. The two main factors necessary for success in the treatment are, first, that the growth is accessible to the action of the rays of radium, and, secondly, that the physical condition of the patient is such that they will withstand the treatment. Literature is teeming with the description of the necessary dosage required to treat a growth of a given kind and size. Our experience in the New York Post-Graduate Hospital has been that it is necessary to treat the patient rather than the growth, therefore our doses are based upon the theory that a patient can take care of a certain amount of absorption due to the disintegration of the growth. For example, in treating a patient who has a hemoglobin of 55 per cent. and red corpuscles of only 3,000,000 per c.m.m., it is impossible to use as large a dose of radium at one time as in the treatment of a patient who has a comparatively normal blood count.

The result of radium treatment and the necessary absorption of protein material demands an increased action on the part of the kidney excretion, and it seems poor judgment to treat a patient with low phenolsulphonephthalein percentage with a lrage amount of radium at one time. To illustrate:

Mrs. R., admitted August 27, 1920, Post Graduate Hospital, service of Doctor Thomas Cherry, presented a normal urinary output but her blood examination revealed a hemoglobin of 45 per cent. Sahli; red blood corpuscles under 3,000,000; white blood corpuscles, 12,600; the differential count was unimportant. The chief complaint was of a constant vaginal bloody discharge. Upon examination a large mass was found rising at the site of a previous complete hysterectomy. Radium therapy was not indicated because of the patient's blood condition and it was suggested that a transfusion be done. 500 c.c. by citrate method was given. On September 8 the blood report showed 55 per cent. hemoglobin; 3,200,000 red blood corpuscles, and 21,000 white blood corpuscles. The patient was then treated with four 12½ mg. needles inserted into the mass. On September 21 the patient reported that she had had no bleeding and was much improved generally. The blood examination showed 3,968,000 red corpuscles, 14,800 white corpuscles, and hemoglobin 60 per cent. Sahli. The patient continued to improve and reported at the clinic on May 27, 1921, having gained over ten pounds in weight and with a comparatively normal blood picture.

Mrs. R., admitted August 28, 1919, to the New York Post Graduate Hospital, service of Doctor Thomas Cherry. Blood examination: red blood corpuscles, 2,776,000; hemoglobin, 70 per cent. Talquist; urinary examination revealed albumin and casts. Chemical blood: urea, 49.6; uric acid, 10; creatin, 13; sugar, 0.159. Phenolsulphonephthalein examination revealed no coloration at the end of four hours. The chief complaint was of vaginal bleeding. Upon examination the diagnosis was made of carcinoma of the cervix involving the anterior bladder wall. The low blood count with the picture of an arteriosclerotic kidney made it impossible to hope that any benefit would come from radium therapy. Knowing the hopelessness of the condition, the family insisted upon the application of radium. 30 mg. was inserted against the cervix for a period of ten hours. The patient became noticeably worse and on the 17th of September examination showed: urea, 107; uric acid, 11.7; creatinine, 20; sugar, 0.142. The blood picture was: red corpuscles, 1,632,000; hemoglobin, 30 per cent. Sahli; leucocytes, 7,040. The patient was discharged on the 28th of September and died the following month.

Experience has taught us that a patient presenting a hemoglobin of less than 50 per cent. or a red count under 3,000,000, is not considered a case for radium therapy. From a urinary standpoint a phenolsulphonephthalein excretion of less than 50 in two hours is considered a contraindication for radium therapy.

To combat the toxemia which always exists after a treatment with radium, soda bicarbonate and soda citrate have been our chief aids. Sodium bicarbonate is given in dram doses, t.i.d. for at least a week after treatment, sodium citrate, in 15 grain doses every three hours. It has been our habit

also to give iron in some form either intravenously, subcutaneously, or orally. A liberal diet is also prescribed and constant attention paid to the increase in bodily weight.

Radium Therapy.—For convenience I will discuss the use of radium under five headings: First, superficial cancers; second, oral, laryngeal, and esophageal growths; third, uterine cervical and vaginal growths; fourth, rectal; fifth, breast.

Superficial Cancers: The basal cell carcinomas are in the majority of the cases very rapidly benefited by the use of radium. The squamous cell carcinomas are more difficult but unless metastasis has occurred over large areas we feel that the disease may be arrested in the majority of cases. Technique of superficial growths; needles ranging from $7\frac{1}{2}$ to $12\frac{1}{2}$ mg. are inserted through the growth, to each centimeter of space a needle, and are kept there for a period of one hour. This treatment is supplemented by using a tube of 25 to 60 mg. applied over each area of about two centimeters square for not more than one hour. These tubes are screened with a millimeter and a half of brass and one millimeter of soft rubber. If necessary, treatment is repeated but not oftener than once a month.

Mouth, Throat, and Esophagus: Our treatment in these cases has been the application of a 10 mg. needle inserted deeply into the growth which is allowed to remain from one to four hours in each centimeter of growth. In many of these cases we had marked diminution in the tumor mass, but in few cases did we escape infection which has proved more disastrous than the original growth. In the past six months we are inclined toward gamma ray therapy and feel that our results are more favorable. Technique: a tube from 60 to 100 milligrams, screened with a millimeter of gold and two millimeters of hard rubber is applied over the growth for one hour daily. Treatments are continued for one month and are then supplemented by external treatment along the glands of the neck, raying each centimeter for approximately 600 mg. hours. This treatment is repeated monthly as often as necessary.

Carcinoma and sarcoma of the tonsils are treated with needles, and if we can prevent infection results are good. Laryngeal cancers have done poorly from a standpoint of cures. Technique: introduction of a needle, containing 10 mg. of radium, by a member of the throat department while the patient is in a suspended position. These needles remain from one to four hours, depending upon the size of the growths. Cross firing externally with a tube from 100 to 125 mg. radium to each two centimeters square. These cases do very well from a palliative standpoint, but sooner or later in nearly all our cases we have noted infection. Formerly we did a preliminary tracheotomy in all laryngeal cases, but because of infection we have discontinued its use and our results are far better. Occasionally after the introduction of the needles hemorrhages have occurred, and in one case this proved fatal. The esophageal cases are at present treated with a special tube made of one millimeter thickness of gold and one millimeter of hard rubber. Attached to this container is a silver wire one millimeter in diameter. Technique: after preliminary *x*-ray examination, the patient is suspended and under the direction of the specialist an esophagoscope is introduced and the radium tube containing from 60 to 100 mg. of radium is introduced as far as possible into the growth and allowed to remain in place for six hours. This treatment is repeated monthly. We can report no cures, but we have four patients who at the present time are able to swallow solid food, and from a palliative standpoint are greatly improved.

Uterine Growths: The technique consists of the introduction of a 60 to 100 mg. tube into the cervical canal. If only one centimeter of tissue is estimated to be involved, 600 mg. hours are given. If more than a centimeter of tissue is infiltrated 2,400 mg. hours are given at one treatment. This treatment is repeated if necessary at the end of from four to five weeks. In certain cervical cases needles of $12\frac{1}{2}$ mg. each were inserted into the cervix, four to six needles being used at a time, and the treatment given for a period of six hours. At the end of two months, if the cervix shows evidence of repair and becomes movable, we suggest a complete hysterectomy and that the patient be returned for post-operative radium treatment at the end of four weeks. Cases of this class are also cross-fired, using from 100 to 150 mg. of radium over the abdomen for 24 hours. Carcinoma of the uterine body we feel is purely surgical, but we suggest ante-operative treatment with a tube of 100 mg. of radium introduced into the uterus for a period of twenty-four hours. Recurrent cases do very poorly and although it may be possible to relieve pain, hemorrhage, and discharge, we have seen no complete recoveries.

Rectal Growths: Much progress is being made in the treatment of cancer of the rectum. Formerly infections have played a great part in our failures and we now advise a preliminary colostomy in all cases of carcinoma of the rectum which are assigned to our department. Technique: needles containing $12\frac{1}{2}$ mg. of radium are inserted under either local or gas and oxygen anesthesia. These needles are applied one centimeter aport once a week for four weeks, and remain in place from six to twenty-four hours. The patient is allowed to rest for a month and then it is usually possible to have some idea as to the amount of further treatment. We also use a tube screened by one millimeter of gold and one millimeter of hard rubber, especially made, containing from 60 to 100 mg. of radium, used daily for one hour. This method has been adopted to prevent sloughing and toxemia, which occurred when we used massive doses at one time. Our experience as to dosage has been that a usual growth will require 600 mg. hours of gamma ray therapy to every centimeter square. It is important that the growth be thoroughly irrigated at least three times a day and it is our habit to use a permanganate of potash solution, 1-3000, as irrigation, two or three quarts daily. This is supplemented by a washing out morning and night with a 3 per cent. soda bicarbonate solution.

Carcinoma of the Breast: Class E, or recurrent cases, do well under radium therapy in proportion to the carcinomatous involvement. These cases can be considered only from a palliative standpoint. Early cases show good results. Technique: Under

either local or gas and oxygen anesthesia needles containing 12½ mg. of radium are introduced into the mass and are allowed to remain in place from six to twenty-four hours, depending upon the size and density of the growth. The chest wall and axillary space, the supra- and intraclavicular spaces are divided into areas, two centimeters square, and are radiated with a tube screened with one and one-half millimeter of brass and one millimeter of soft rubber for 300 to 600 mg. hours. The treatment may be repeated at the end of a month and it is suggested, in every case, that the breast be removed by an elliptical incision and that the axillary space be undisturbed, leaving all postoperative treatment in the hands of the radium therapist.

Bladder and Prostatic Cases: In bladder growths a preliminary suprapubic opening is suggested and the method established by Doctor H. G. Bugbee of New York is followed. Ten mg. radium needles at a distance of one centimeter apart are introduced and allowed to remain in place for six hours. An indwelling catheter is introduced into the suprapubic opening and allowed to remain in place for at least a month. At the end of a month the bladder, under gas and oxygen, is explored again and if any evidence of the growth is noted the needles are inserted in the same manner as before. This improved technique has been in force too short a time to report permanent cures, but that the initial growth has been removed in each instance seems encouraging as to the future outlook.

Prostatic growths are treated in like manner, and through a suprapubic opening, radium needles attached to long handles, are inserted into the prostate through the bladder and allowed to remain in place for six hours. This treatment is supplemented by the introduction of radium needles through the perineum into the prostate which are allowed to remain from three to six hours. The temporary results in carcinoma of the prostrate are apparently encouraging, but again the time is too short to note the permanence of the result.

In summarizing I wish to emphasize:

1. The necessity for closer cooperation so that the early use of radium may be proven.

2. The need for further experimentation to determine the action of radium on abnormal tissues.

3. My personal belief that radium should be used in all malignancies before and after surgical operations.

4. The relative value of radium emanation and salts of radium to be determined only after further experimentation.

5. The question of whether surgery or radium shall be considered more efficient in the treatment of malignant growths of the cervix and rectum.

116 East Fifty-third Street.

Garlic as a Hypotensive.—Evidence accumulates that products containing the active principle of garlic are hypotensive. In the laboratory they are able to reduce the tension and slow the pulse for a considerable interval. There seems to be a selective action on the vagus nerve. Tincture of garlic will produce the same result in the clinic on mankind. There has been no suggestion to employ the drug in hypertension and no account of results obtained in that condition.—*Gazette des Hôpitaux.*

ANTHRAX AS A NON-OCCUPATIONAL DISEASE.*

WITH SPECIAL REFERENCE TO ITS SHAVING-BRUSH ORIGIN.

By LOUIS HANNAH, M.D.,

Sylvania, Ga.

Anthrax (French, *charbon;* German, *milzbrand*) is primarily a disease of animals and most frequently affects those of the herbivorous class, especially cows and sheep. A number of laboratory animals, such as white mice, house mice, guinea pigs, and rabbits, are highly susceptible. Man is susceptible in varying degree, and with possibly few exceptions acquires the disease, directly or indirectly, from the lower animals. Such animals convey the infection in the capacity of hosts as well as victims of the malady, for beasts are known to harbor the germs for years without contracting the disease themselves.

The origin of anthrax is said to be lost in antiquity. It has been identified with the plagues of Egypt, and some authors believe that allusions to the disease are to be found in Homer. To enter into its history and world-wide statistics would lead us far afield of the purpose of this paper; but suffice to say here the disease is ubiquitous, its worst ravages being reported from Asiatic countries—mainly Siberia, Asia Minor, China, and Persia. Russia and Italy are the most seriously affected of the European countries, while Germany, France, and England, prior to the period of the world war, were comparatively free from the disease. In the United States, anthrax has been known for about a century and has occurred, in both sporadic and epidemic form, in nearly every State, chiefly in the Mississippi Valley, Gulf States, a few Western States, and in the East, principally New York, Delaware, Pennsylvania, and Massachusetts. Until the past few years the great majority of cases occurred among the lower animals, and only recently has the disease become recognized as an occupational and social menace to this country. To indicate its frequency, it might be stated that more than one American physician has had as many as forty cases in individual private practice in the course of from six to eight years.

It is of singular note that the prevalence of other infectious diseases (discovered long since anthrax) has ceased to attract extraordinary attention, while anthrax, which afforded us our first knowledge of bacteriology, has only recently attained prominence in this part of the world. The occurrence of this disease formerly was regarded more as a foreign scourge, affecting principally beasts and infrequently man, and was commonly prevalent only in Asiatic and a few European countries. Today, however, it concerns our own country as an industrial problem, and lately we have been confronted with the danger of remote infection from various sources of inoculation. In other words, our attention is directed to sporadic cases of this affection which bear no direct relation to industrial pursuits. The disease in man has been, in the large majority of instances, of occupational origin, arising from con-

*Read before the Screven County (Georgia) Medical Society, at Sylvania, Ga., August 25, 1921.

tact with animals or their carcasses, but most frequently from handling materials obtained from infected animals and used in the manufacture of such as woolen, leather, and hair goods, and artificial manure. Materials imported from Asiatic countries especially are prolific sources of the infection. Not only raw, but the finished products as well (such as leather, shoes, toilet brushes, hair braids, hair mattresses and pillows, etc.) are carriers of the disease, though much less frequently. It is possible for persons to become infected either by mere handling of such products in transit or through the ultimate utilization of them. Furthermore, instances are recorded of the infection in humans being acquired by coming in contact with grain, such as wheat, which was supposed to have been contaminated by infected animals or animal products. The germs of anthrax have been found to lurk in all secretions of animals, including urine, feces, saliva, and milk, from which they may be disseminated by flies and other sucking insects. The disease is even known to have occurred from contact with pet animals which had been feeding on diseased carcasses. The liability to infection of wounds or incisions from anthrax-infected catgut is common knowledge to students of surgery. Of all sources, however, of this disease the greatest danger is said to repose in hides and wool.

Since the advent of the world war, an added danger to mankind from anthrax in the form of cheap shaving brushes (especially the horsehair variety), has been introduced into the United States in by far the greatest measure from Eastern countries, whence horsehair and various bristles were hastily shipped, without the previous usual disinfection because of the urgent demands that accompanied hostilities. Following the outbreak of shaving-brush anthrax among American soldiers during the war, a number of such cases have been reported from time to time, which becoming scattered as reports indicate, it is not at all improbable that unless radical measures are instituted against the careless manufacture of these brushes, we shall be seriously confronted with anthrax as a social, or non-industrial, as well as an industrial problem. Up to June, 1920, there were recorded in this country twenty-four instances of shaving-brush anthrax, in six of which bacilli were isolated from the brushes. But this number, in all probability, does not represent every case that has occurred, because physicians generally have not in the past been aware of this peril in shaving brushes, and thus failed to recognize the disease. One observer, from investigation of the records of Charity Hospital in New Orleans, has stated: "We are forced to the conclusion that many cases of anthrax must have died in private practice, as well as in our public institutions, under the diagnosis of erysipelas, cellulitis, carbuncle (ordinary), blood poisoning, etc."[1] The disease is even said to have been confounded with diphtheria.

Concerning the shaving brush as a source of danger from anthrax, Hubbard[2] regards the use of new brushes made of horsehair or mixtures containing horsehair as a matter "calling for prompt and drastic action by our public health authorities." It is even suggested that all horsehair shaving brushes be taken off the market and that their future manufacture be interdicted. Though horsehair varieties are the most seriously incriminated, should not *all* shaving brushes be regarded with keen suspicion? It is with the non-occupational phase of anthrax, and with the shaving brush in particular as the chief offender among finished products conveying the disease that the writer is herein concerned.

The recognized types of anthrax, according to Andrews, are malignant pustule, malignant edema, pulmonary, and gastrointestinal anthrax. The first two also are classified as external anthrax, in which inoculation occurs usually through a scratch, cut, or abrasion in the skin, and the latter two as internal anthrax, which arises either from inhalation or from ingestion of the germs with dust particles or food. The disease, as manifested from shaving brush inoculation, concerns, of course, only the external variety. Of the cutaneous lesions, those arising in the cervical or adjacent regions are most serious, the mortality in such cases approximating 50 per cent. It is obvious, therefore, that the shaving brush as a source of the malady is particularly dangerous, because the victim is invariably inoculated about the face or neck, where the brush is applied.

CASE.—S. D., a negro farm laborer, 32 years of age, and married, was brought by automobile to my office from his farm, a distance of six miles, on last April 30. Though he was able to maintain a sitting posture in spite of the rugged trip and walked alone to the office, on arrival the patient exhibited signs and symptoms of a most serious malady. Attention was first attracted to his agonizing dyspnea and gurgling of fluid in his throat. On closer inspection I discovered a large lesion about the center of the anterior surface of his neck, which proved to be a flattened, indurated, and necrotic papule, the size of a half dollar. Forming the core of this lesion was a black eschar, surrounding which were coalesced vesicles, a reddened areola, and a generalized subcutaneous edema. The sore caused no pain, but only a slight itching. The patient's neck was swollen to about twice its normal size, and there was such marked swelling of the shoulders, arms, and thorax, that the overlying skin was very tense and glistening. The edema was fluid, producing no crepitation, but pitting on pressure. His facial expression was anxious and respiration so embarrassed from edema, and possibly inflammation, of the larynx, that it was difficult to obtain a history of the case. He was covered with a cold, clammy perspiration; his tongue was heavily coated. His temperature could not be taken, on account of the necessity of keeping his mouth open to breathe. Enlargement of the lymphatic glands could not be detected; his pulse was imperceptible; and his blood pressure did not register even any oscillation of the instrument's needle; all of which were probably due to the extent of edema. Examination of the patient's blood showed hemoglobin 70 per cent., malaria negative, and blood picture indicating marked secondary anemia, doubtless the result of an anthracemia. Analysis of the urine proved negative. His past history was excellent, with the exception of an attack of gonorrhea. No family history could be obtained. The present history is as follows: On Sunday, six days before coming under the writer's observation, the patient while shaving cut a small pimple at the site of the present lesion on his neck, of which mishap he thought nothing at the time. The following day the injury had developed into a very small, apparently insignificant sore, which subsequently progressed daily in size until it presented the appearance observed by the writer. On the third day after shaving, the patient stated that he had a severe chill and high fever, and the next day became aware of the swelling and slight dyspnea, but did not consider it imperative to consult a physician until two days later (six days after shaving), when he came under my care.

The patient was given stimulants, and a hypodermic of quinine because of the chill and the prevalence of pernicious malaria at this season. But the serious nature of his affection was not at first determined. The lesion on his neck was considered as possibly syphilitic, with a superimposed, unknown, malignant infection. He was also given antisyphilitic treatment, but with no hope of recovery, as he was already in practically a moribund condition when brought to my attention. The patient died two days later—nine days after onset of the disease, and at the time of his death the edema had extended to his thighs. A postmortem clinical diagnosis was derived from the association of the characteristic cutaneous lesion with the use of a new shaving brush, and from the malignant type of edema. Later this diagnosis was verified by isolation of anthrax bacilli from the shaving brush which the patient had used. Seventeen other brushes from the same lot were also examined by cultural methods, with negative results. Grateful acknowledgment is made to Dr. T. F. Sellers, of the Georgia State Board of Health, for identification of the organisms in this case and the resulting bacteriological diagnosis. It might be well here to state that antianthrax serum could not have been obtained sufficiently early for administration in this case.

All articles, including lather brush, used in shaving by the patient, were "brand new," and had been used for the first time. They were purchased from a local 5 and 10 cent store, whose stock is supplied entirely from headquarters in New York, indicating the Northern origin of this case. There was no brand mark nor manufacturer's label on the brush used in this instance, but an effort is being made by health authorities to ascertain the source of this lot of brushes through the buyers in New York, while the remaining ones of the lot have been taken off the market by local retailers.

Comment.—The interesting and possibly unusual feature of this case was the extent and malignancy (as to effects) of the edema. Malignant edema, as an individual type of the disease, is said by those who have made a special study of anthrax to be characterized in severe cases by "redness, vesication, and a gangrenous appearance of the skin," and especially by edema of the eyelids, and by absence of a pustule. In the present instance we have a combination of both malignant pustule (so-called) and generalized subcutanous edema, which though absent from the eyelids and presenting none of the skin changes described above, certainly was malignant in its extent and effects. I know of no other instance of this disease which exhibited such universal edema.

As to the recognition of anthrax, one could hardly be discredited for an untimely diagnosis, at least in this section of the country, because of the rarity of the disease and the inattention of public health authorities in the past to its possible prevalence. The records of anthrax in Georgia, according to a report of Dr. T. F. Sellers,[3] read before the Medical Association of Georgia in 1919, show that the disease was practically unknown in this State prior to the occurrence of three cases at Camp Hancock in June and July, 1918, two of which were traced with certainty to shaving brushes. The following year, in February, a case was reported from Camp Gordon, and in April of the same year another, both of shaving-brush origin, was reported by Dr. Shellhouse, of Calhoun, Georgia. A bacteriological diagnosis was established in all of these cases. The total number of cases of anthrax in Georgia, therefore, of which statistics are available, comprises, in addition to the one under consideration, the five instances cited above. It will be observed also that the reports are confined strictly to the shaving-brush variety. These figures indicate the rare incidence of the disease and that, prior to recent military activities, it was either unknown, unrecognized, or unannounced in this State. The small incidence of such a serious malady, however, should not discredit its danger, and it is imperative that the public be especially cautioned in regard to the potential evil of cheap shaving brushes. A campaign against this source of anthrax is now being formulated by the Georgia State Board of Health, which would be very timely for all other States of the Union to inaugurate, in cooperation with the Federal Health Service and the American Association for Labor Legislation.

As this article goes to press, the writer is informed of the recent occurrence in New York City of another case of shaving brush anthrax which adds emphasis to the importance of this dread disease as a non-industrial problem. In this instance, death resulted in three days after shaving, notwithstanding specific treatment in one of our best hospitals and at the hands of competent men. The victim was a former congressman—one of that social class who would not be expected to employ a cheap variety of shaving brush—which impresses us with the universal risk attendant upon the use of any unsterilized animal hair brush for shaving; by "unsterilized" we refer to its literal meaning (implying that an article is either sterile or unsterile), and not to uncertain measures employed for sterilization. The rapid fatality in this case, as well as the patient's ignorance of the seriousness of his condition until too late (which is practically always the circumstance), also should certainly arouse the attention of all public health authorities to the necessity of prompt action in the matter of education and warning against anthrax.

A SPECIFIC CURE FOR PNEUMONIA AND PULMONARY TUBERCULOSIS.*

By SAMUEL STERN, M.D.,
ATLANTIC CITY, N. J.

To claim a cure for pneumonia[1] and pulmonary tuberculosis is both presumptuous and startling, particularly so in view of the many discredited pretenders in the past. Therefore, to verify my claim of a cure, the following researches are submitted based upon fundamental and accepted scientific facts which can be readily substantiated by reference to any standard text on the subjects quoted. In the facts I am about to present, I will first briefly outline the normal body functions and their perversions, which can and do occur, resulting in pathological processes of these diseases and it

*Read by invitation, Lancaster County Medical Society, Lancaster, Pa., April 6, 1921.

may be noted how closely they follow and are associated with health and disease and direct the way, scientifically and successfully, to apply a cure for pneumonia and pulmonary tuberculosis.

Health: Gould's definition. That condition of the body in which all the functions are performed normally and equals normal physiological state.

Normal Physiology.—The body as a whole may be described as a composite mass of cells of complex chemical construction, each cell having its function which if not directly is indirectly correlated. All these cells are dependent upon body metabolism for their growth and sustenance. This is maintained in various ways, the usual method being through the blood. As the blood travels through all the tissue and organs in the body, it follows that it may select or eliminate any substance it may contain. The blood carries in solution or suspension the various products of metabolism or assimilation, both endogenous, internal, and other secretions, and exogenous foods and gases, whereby through proper interchange of absorption and elimination it is enabled to maintain the harmonious relations existing in health. Now note that any interference therewith in any manner is followed by functional or physiological derangement which, if continued, will induce physiological defenses in which the law of compensation undoubtedly becomes a factor and, if prolonged or should the compensatory efforts fail, organic or pathological changes must inevitably occur.

Functional changes of the organism may be independent of or associated with pathological processes. It is evident, however, that all pathological changes, in addition to tissue alterations, are accompanied by physiological variations. Fischer's[2] postulate here deserves emphasis: "The transition from the physiological to pathological is not abrupt, although an imperceptible one." Heretofore, the failure to observe the physiological changes associated with the pathological findings have contributed in part to our failure in the treatment in these and other diseases. The pathological processes which invite these physiological alterations should be studied seriously and intensively so that we may be enabled to treat the various diseases intelligently and successfully.

The blood, the body's most vital element, is one of the chief factors in pneumonia and pulmonary tuberculosis and is physiologically well worth close attention and consideration. Physiologists describe the blood as a fluid or plasma holding in solution or suspension salts, cells, and other organic and inorganic matter. It is alkaline or neutral in reaction—the sodium and potassium carbonates and phosphates are its principal alkalies. The alkalies constitute an integral part of the protoplasm, keeping in solution—note well—the albumins with which they are combined and modified. Von Noorden[3] believes the body organism has a tendency to maintain its own alkalinity and serious consequences may follow its reduction. Of alkalies' other qualities I will refer to later. The plasma also contains fibrin which under normal conditions remains in solution. Its precipitation within the body tissue usually accompanies some pathological processes, for instance, its presence in the alveolar spaces in pneumonic states. As regard the causes of fibrins — coagulation or precipitation — one authority contends that inflammation is essential to coagulation and precipitation and points to fibrin ferment produced by this change as the factor that produces this result. Others think cellular destruction, whatever the cause, is the means of liberation of fibrin ferments. Fischer attributes it to acids or excess of alkali, principally the former. Another cause is the presence of any foreign body within the blood. No serious attention, however, need be paid to the academic discussion relative to the merits of the various theories concerning the production of fibrin and its ferments, for at some stage in the progress of pneumonia and pulmonary tuberculosis one or all of these conditions may be present.

Of the cellular elements we need note only the red blood cells. The chief function of these corpuscles is that of a vehicle for gaseous elements. They carry oxygen from the lungs to the tissues and promote the elimination of carbon dioxide from the metabolic processes of the body. To properly provide for these changes hemoglobin and alkalies are provided.

Hemoglobin may be described as a highly complex protein body contained within the red blood cell. By virtue of its iron content it is very stable, being enabled to absorb oxygen but not to oxidize it. Combined with its powers of ready dissociation, it facilitates both physiological processes, absorption of oxygen to provide for oxidation—the body's chief source of energy—and elimination of carbon dioxide, one of the most important waste products of metabolism.

Mathews[4] recognizes two kinds of oxidation occurring within the living matter—aerobic and anaerobic. Aerobic from exposure to air, absorption from the lungs; anaerobic, produced by reduction of foods or changes in body metabolism. Any interference with these most vital physiological processes may be attended by serious consequences to body metabolism. These elements, as I will show, are very important factors in the production and correction of pneumonia. Oxygen free in the blood is in union with hemoglobin as oxyhemoglobin.

Carbon dioxide and carbonic acid are principally waste products of tissue change and the metabolism of digestion or of any oxidative process. Retention within the body of these waste materials will lead to serious harm and as such are important contributing factors in the processes of pneumonia. As already noted, the absorption of oxygen and the elimination of carbon dioxide are dependent upon alkalies, the chief being the sodium and potassium carbonates and phosphates.

A study of the method of exchange of these agents so vital to cellular life shows that the blood corpuscles containing carbon dioxide and carbonic acid in solution or suspension, as phosphates, carbonates, or bicarbonates of sodium and potassium, or as methemoglobin, convey this substance to the excretory organs of the body. We are chiefly concerned with the lungs and their method of exchange of carbon dioxide, carbonic acid, and oxygen.

According to Graham's[5] law, the diffusibility of gases is inversely proportional to the square root of their densities. Therefore the lighter gas, air with its oxygen, will descend. Moreover, the tension of the oxygen of the air is higher than that of

the blood, and the tension of carbon dioxide of the blood is higher than that of the air. Necessarily, therefore, the oxygen of the air passes through the lungs into the hemoglobin in exchange for carbonic acid and carbon dioxide. This sets free the alkali with which it is in suspension or solution. The alkalies are thus liberated in the blood to saturate other carbonic acid affinities. The oxygen is hereby procured and this necessity to all oxidative processes is provided for.

Consider now the results of any interference with this cycle of exchange of oxygen, carbon dioxide, carbonic acid and the consequent liberation of alkalies. First, the chief source of supply of oxygen for oxidative purposes is withdrawn either partially or entirely. Mathews notes that this produces cellular acidosis. Carbon dioxide, if retained, owing to its affinity for water, increases the carbonic acid content of the blood and tissue, thereby producing acidosis. Oxidative processes are inhibited which secure molecular and tissue changes and alter viscosity. If delayed in elimination, these changes promote tissue asphyxiation. Free alkalies are also lost to the system by reason of their combination with carbon dioxide and carbonic acid to assist in removing these waste products from the tissue. This loss is also to be noticed in withdrawing an essential physiological element in maintenance of the albumin in solution, and maintaining normal viscosity. Do we not, therefore, at once interfere with the normal physiological equilibrium and, if persisted in, insure pathological processes? We do. And this is in part the modus operandi which, if continued, readily induces other physiological changes referred to later, which, when completed, present the pathological picture of pneumonia and tuberculosis.

The physics of pneumonia is also not to be ignored. The laws of physics, like those of chemistry, are universal. Though they may be coincident, they are undoubtedly independent and, as such, play an important rôle in normal and perverted physiological states. In discussing blood viscosity, Hemenway[6] says that when the viscosity is increased the velocity of the blood current will be reduced, unless the force behind it is increased. It requires four pipes with a diameter of 1 inch to equal the capacity of 1 or 2 inches. Since the circumferential friction is increased inversely with the diminution in the square of the diameter of the vessel, it is easy to see that the smaller the vessel the greater will be the retarding effect of viscosity on the blood current. This effect is especially noted in the capillaries through which all the blood of the body passes; complete capillary stasis may ensue. Later, in his article, Hemenway adds, given obstruction through the capillaries with heart power normal or above normal, the tendency is to force the more fluid portion of the blood into the tissue or to produce rupture of the weaker vessels.

Is not this suggestive of the cause of cardiac failure so common in pneumonia? Would it be rash here to suggest that the increased blood pressure so indicative of cardiac failure is an index of the degree of altered viscosity, or are we to assume it to be an incident of the disease? To me it asserts itself as cause and effect and is another factor in the establishment of this physiological perversion. To digress from my subject it may be asked, Is increased blood pressure in clinical medicine a symptom of the complex of the disease in question? Is it a disease *per se?* Or is it not, as in pneumonia, the physical effect of altered viscosity? Here surely is a fertile field for investigation. Mathews cites a 4 per cent. increase of viscosity by variations of temperature of 5°, surely within the range of most febrile states. The same author adds that carbon dioxide is a factor in increasing viscosity, while oxygen diminishes it. That there is a surplus of the former and a deficiency of the latter I shall later show.

Of other important factors of viscosity the colloid bodies are noteworthy. All the factors and theories concerning the colloidal state need not be discussed here. They are accepted facts, however, since Graham's[5] contribution in 1851, and they constitute a large portion of the body protoplasm; they are susceptible of physiological and physical variation which, under favorable conditions, assume pathological importance.

Quoting Noyes, Fischer distinguishes two types of colloids: those which are viscous, gelantinizing, and not readily coagulable with salts—colloid solution—and those which are nonviscous, nongelatinizing, and not readily coagulating with salt—colloid in suspension. Fischer states that the essential difference between the two groups resides in the relation of the colloid to the solvent. The first type united to much solvent is lyophilic; if soluble in water, hydrophilic. The second group is called lyophobic. The hydrophilic class contributes the larger part of the body protoplasm. Of the colloids with which we are chiefly concerned the pulmonary cells deserve only passing mention. The blood plasma and corpuscles cause us most concern. I have already called attention to the presence of fibrin and serum albumin in solution with alkalies. To this we should add fibrinogen, serum globulins, lipoid and fat-like bodies, all colloids in soluble state; it is upon the colloid bodies that Fischer builds. He believes them subject to changes and says that they swell in the presence of acids. Hydration and dehydration are the results of the influences of water. Mathews calls attention to the reaction of all protoplasm as generally being faintly alkaline (personal opinion amphoteric).

In speaking of the physical and chemical changes which ensue in protoplasm when its reaction is rendered less alkaline or more acid, Mathews says that they are extremely important and profound. That acids are supplied to these bodies, I shall show. Combine this with the withdrawal of alkalies and we incidentally supply in part the means to produce coagulation or gelatinizing of these colloid states (gel) and confirm Hemenway's findings that altered viscosity may show its effect locally, namely, gelatinizing state of colloids in lungs and these when present and completed add to the physiological alterations that produce the pathological state of consolidation in pneumonia.

Disease is defined by Gould as a disturbance of function or structure of any organ or part of the body "which is typical of a pathological state." Let us now review the pathology of pneumonia and pulmonary tuberculosis.

Pathology of Pneumonia.—The three stages,

congestive or red hepatization, consolidative or gray hepatization, and resolution, require only passing notice.

Histology.—All standard textbooks note that in the congestive stage there are blood, distended capillaries and alveolar tissue. In the consolidative state the picture is altered to include fibrin, cellular and granular debris, red and white cells, bacteria and serum. Resolution adds to this picture mainly the liquefaction, necrosis, and its mucoid character.

Bacteriology.—We need be little concerned with the many cocci or bacilli, distinguished by their presence or their supposed responsibility, as causative factors in pneumonia. Biochemically they are classified by Vaughan[7] as essentially particulate specific proteins and in his work on protein-split bodies he lays great stress upon bacteria as particulate proteins producing aminoacids. Abderhalden's[8] defensive ferments confirm Vaughan's work in aminoacids and, in accounting for the failure to provide specific toxins or vaccines to combat their effect, states that 40,200 distinct chemical bodies may be produced from eight bodies, elements or substances. Any single chemical protein of the aminoacid type contains four elements: carbon, hydrogen, oxygen, and nitrogen. It is, of course, reasonable to presume it capable of producing at least a few acids or a single aminoacid. Should this fail, Abderhalden again comes to the rescue: "We can well imagine decomposition of the bodies of dead microorganisms to occur without the direct participation of the microbes themselves to give rise to various disturbances in the harmonic host without the microorganisms exerting any direct action." Combine these findings with Mathews' observation that every acidosis is combined with proteolysis in the cells and the appearance of ammonia and we surely have proof presumptive of the primary and secondary action of bacteria in producing pneumonia.

Pulmonary Tuberculosis.—As a foreword, first I make no claim for a cure in the advanced types of this disease, with marked cessation or cavity formation. To do so would at once justly invite suspicion. However, in the early cases the socalled incipient or latent types, particularly of tuberculosis, without destructive lesions are amenable to this cure.

It is not within the scope of this paper to discuss fully all the lesions which may and do occur in pulmonary tuberculosis, though a general description is in order of the primary state which exists in the onset of this disease and if allowed to persist may and will produce any or all of the varied types and states described. As prevention is the keynote of present-day medicine, it follows that in the early diagnosis and proper treatment of pulmonary tuberculosis the more serious consequences of tuberculosis may be eliminated.

Pathology of Pulmonary Tuberculosis.—The gross pathology is one of catarrhal pneumonia in the capillary bronchitis which exists. Here all the histological findings already alluded to plus the tubercle bacillus, the provocative agent, may be found.

Coplin[9] states: "Associated with the development of the tubercle there is inflammation of the epithelial lining of the vesicles constituting either a true pneumonia or bronchopneumonia. So that a lobe, or rarely both lungs, may represent some form of the bronchopneumonia or what closely resembles lobar pneumonia." In confirmation of this, any one of us can surely recall his autopsy observations and experiences in which the small miliary tubercle was central to a well defined lobular pneumonic area.

Vaughan in his work upon this disturber of our health and happiness has separated glutanimic acid and other split proteins from the tubercle bacilli which add specifically to our knowledge of this disease. Add to this the secondary infections usually present, the staphylo- and streptococci, the pneumococci, and we again have all the factors already accounted for in pneumonia.

We may now profitably review and correlate these studies in physics, physiology, pathology, bacteriology, etc. The occurrence and progress of active hyperemia or congestion in pneumonia and tuberculosis is dependent upon weather exposure and bacterial invasion. This is followed by increased arterial influx of blood in the capillaries which, if continued, alters the normal densities and tension of oxygen and carbon dioxide in the effected alveolar air. The failure of proper interchange of gases, owing to the loss of equilibrium in tissue tension, density, free oxygen and alkali effects this exchange. The compensatory powers of the body protoplasm now enter and as long as this is equal to the occasion, physiological processes, though retarded, may be completed; with interference continued, the physical factors add to the already labored functions.

I have spoken of altered viscosity first, by physical interferences with capillary circulation. This adds to the carbon dioxide retention and failure to supply oxygen to already overburdened and undernourished tissues. This provides the acidosis of tissue, according to Mathew's views, which I have noted, as due to faulty oxidative processes and an increased ammonia output by proteolysis, as cited by Vaughan and Mathews. It is probable that at this stage the growth of bacteria has sufficiently advanced to supply the aminoacids of Vaughan and to disturb the harmony to host as quoted by Abderhalden, which adds to the already overburdened parts; edema of the pulmonary or alveolar tissue being a factor of obstruction to capillary circulation in the affected area, continues this state. It increases the retention of carbon dioxide, it diminishes the oxygen supply, it advances the production of carbonic acid, and the withdrawal of free alkalies —all these factors contribute their share in the embarrassment of pulmonary tissue and produce at this stage fully advanced congestion.

We now gradually emerge from psysiological to pathological conditions, confirming Fischer's postulate of imperceptible transition from normal to pathological. Continue this lung embarrassment and the colloids add their share of troubles; hydration first, withdrawal of alkalies, advancing acidity, tissue and cell proteolysis, aminoacids of bacteria, later hydration and passage from soluble colloid state to gelatinizing state or coagulation of the blood within the affected area, *i.e.* the consolidative state or red hepatization of pneumonia. As to fibrin, somewhere in the latter stages of this

evolution all the processes for precipitation of fibrin already noted, namely inflammation, acidity, cellular destruction, proteolysis, etc., have been provided for. Other probable compensatory problems are the giving up of the sodium and potassium bases of the sulphates to become sulphides and sulphuric acid. The latter, according to Bunge," would also be a product of hypoalkalinity and the perverted catabolism of proteins, both present in pneumonia.

At autopsy with section of the lung in pneumonia we would now have the pathological picture of a firm, dark red, dry, granular lung; bulging aveolar spaces of acute lobar pneumonia, histologically showing red and white cells; bacteria, cellular debris and fibrin. As to the cellular content present in this stage, they are the victims of circumstances, like rats in traps, so to speak, enmeshed during the gradual change from soluble gelatinizing solution to coagulation.

The various factors in the production of these diseases having been accounted for, we are now concerned with restoring the diseased state to normal. Here a brief survey of gray hepatization shows this pathological process to be one of the body's defensive efforts at restoration, and the first advancing sign of resolution, which is the body's endeavor to restore harmonic relations.

It is not within the scope of this paper to describe all the changes in the transition from pathological to physiological; I note only that the resolution of pneumonia must be essentially the provision of correctives that the body's efforts to return to normal physiological equilibrium may be accomplished. It should be said that when we are more familiar with the body processes we may well marvel at the wonderful immunity defences and compensations present. I might further add that most of nature's so-called cures can and will later be accounted for in compensatory reactions of the metabolic processes of the body which, though seldom absent, may be delayed. Probably a few of our socalled states of immunity may be accounted for by intensive physiological observations. It is upon these most fortunate circumstances that our mystic and other neighbors often succeed mysteriously where we have failed, much to our chagrin and incidentally financial embarrassment. It is surely not due to any vaunted skill or virtue that they may profess to have.

Treatment.—Empiricism, indeed, has too long dominated our applications of remedial measures. We have surveyed the normal physiological relations necessary to continue and promote health. Attention has also been directed to the perversions and the means by which they have been effected. As recovery from disease necessarily consists in restoring normal functional activities to, or near, the state in existence previous to diseased alterations, it follows that the cure of pneumonia and tuberculosis depends upon a restoration of normal physiological conditions of pulmonary and other tissue metabolism. Here a word of caution: it is neither essential nor safe to provide highly complex, doubtful, or dangerous methods; simplicity may be combined with safety, and what is more to be desired, specificity. All these desirable qualities may be readily at our command.

I have directed attention to the one element, oxygen, as essential to psysiological processes. This important constituent is very essential to all cellular changes. Have we not in the past appreciated this in our effort to supply oxygen directly in our treatment of pulmonary tuberculosis and pneumonia, and indirectly by the open air methods? Cyanosis as evident at some stage reveals carbon dioxide retention and should be provided for by elimination.

Coagulation and consolidation and its production and associated interferences with normal physiological relations has been referred to and demands our attention. Since nature's socalled cure is resolution of these areas, the primary aim is to provide for or to promote this process. As the normal body supplies physiological means to maintain this condition in the healthy state, we can safely imitate her by furnishing these deficiencies.

Here reference to physiological processes informs us that the combination of organic acids of foods, the citrates, malates, oxalates, tartrates and benzoates has, with sodium and potassium bases, the function of keeping in proper balance and solution the various albuminous substances of the blood and body tissue. To supply any of these acids, citric, oxalic, tartaric, while logical, is not without its attendant dangers and limitations and in so doing we ignore fundamental principles of intelligent therapeutics.

This is best expressed by Fischer's thought of the many drugs to be employed. One can foresee, of course, that those will give the best results which can have no specific poisonous effect, and which have the maximum power to restore normal physiological relations. In selecting acids, citric acid seems to have answered most of these demands. If for a base sodium is supplied in place of potassium, we again materially gain and supply all the good features and avoid any possible dangers from careless or ignorant application. Further, sodium is stimulating to the heart and striped muscle tissue. In general, potassium is depressant and in maximum doses may be toxic. Sodium citrate is converted in the system into sodium carbonate, a most essential element to normal body metabolism. As already shown, by this drug we are enabled to promote resolution of the coagulated areas with citric acid—in soda, its base, we are enabled to provide for oxidation by supplying free oxygen in sodium carbonate.

We also provide for elimination of carbon dioxide and carbonic acid which, according to Haldane's[11] newer physiological conceptions, are life's basic factors. We provide for hydration and dehydration accompanying this condition. We keep in solution the albumins essential to normal viscosity. Combine this with the dilution of toxins of the bacteria by virtue of the freedom of use possible with this drug and we need not, therefore, fear the virulence of any bacteria.

All the other physiological and physical factors already alluded to are also provided for. Sodium citrate has served me well and is the drug of my choice; and here a word of caution as to the personal care in the selection of drugs to be used is not amiss. Ordinary commercial drugs are usually chemically impure, the sodium salts often being contaminated with the chlorides and sulphates and iron. Therefore C. P. drugs are in order.

Should nausea and diarrhea occur, Weaver[12] advises the use of paregoric. To counteract this state, my custom is, first, to decrease the dosage one-half to one-fourth, or lengthen the interval of administration before resorting to opiates. I have used the tartrates, potassium bitartrate, which is acid, in my senile cases, where alkaline urine with its attendant ammoniacal decomposition was a factor to be dealt with, insisting, however, that the attending nurse use litmus paper as her guide in its use, and I have played alternately with my citrates and tartrates until my results have been accomplished.

Again in children, or adults with children's temperaments or habits as to partaking of medicine, grape juice has saved the day, for in unfermented grape juice we have the tartrates in a palatable form, and I would add that it is good therapeutics in all cases as a finishing touch to treatment and through the convalescent state. Here a knowledge of the chemistry of foods again comes to our rescue, for the malates in cranberries and apples, given as sauces, are particularly efficacious both for treatment and to give dietary variety and latitude with satisfaction and safety to the patients.

As to the dosage of pneumonia in adults—children in proportion to age—two drams are given every two hours, dissolved in eight ounces of water or milk for the diuretic and diaphoretic effect and to aid gastric tolerance. I never permit less than four to six ounces of fluids in adults, children in proportion, with tendency to larger quantities of liquids.

Some results of this treatment were as follows: Respirations that had been rapid, labored, and limited, with accompanying pain, showed almost immediate amelioration. A respiratory rate of forty to sixty was lowered to an average of twenty-eight to thirty-five and usually with greater amplitude and freedom from pain and distress. Temperature, the usual febrile state, 102.5° to 104.5° F., declined rapidly to 99° and 100.5° F. within twenty-four to forty-eight hours. Results were obtained by lysis, not crisis, within from four to six days without the intense prostration usually accompanying the disease.

Any discontinuation of treatment before five to seven days is usually followed immediately with recrudescence and return to original state. Diuresis and diaphoresis were also obtained. Diaphoresis and diuresis are most pronounced. In the majority of my cases diaphoresis was so marked as to often evoke comment, often concern, lest the patient take fresh cold. For its beneficial effects, we are enabled to draw upon the skin as a valuable aid and excretory organ in the elimination of waste and other products. I speak of carbonic acid and carbon dioxide, etc. Hypodermoclysis is unnecessary and, as Fischer notes, dangerous, because it may and often does invite sloughing.

I would also note that the period of the disease is materially shortened. The individual is relieved of the intense suffering and prostration attendant upon all other methods heretofore tried or suggested, and this within twelve to twenty-four hours after treatment is instituted and continues until recovery is established. Freedom from any complication, such as effusion or empyema, allows me to institute regular diet just as soon as the patient will accept same, omitting only the acids, spices, salad dressings and condiments—which is usually about the third day. Laxatives are administered if necessary.

In my senile and highly toxic cases, I support the kidneys' elimination with half-ounce doses of infusion of digitalis and buchu made fresh from the leaves. Here again I would enjoin the physician against permitting the pharmacist and the manufacturer advising the use of the fluid extracts in providing infusions as is commonly and regularly done. Fluid extracts are not infusions, nor are infusions fluid extracts except to the knave, fool, or impostor. These are dangerous individuals to the physician and his patients and should be carefully avoided or shunned.

In cases marked by troublesome coughs I use heroin and terpin hydrate or codeine in a suitable mixture. I continue my two drams of sodium citrate until temperature, respiration and pulse have remained normal for forty-eight hours. Then I gradually reduce the dose by lengthening the interval of administration and continue the process until the patient is discharged as cured.

In tuberculosis I usually administer sodium citrate, one dram t.i.d. unless febrile or pneumonic processes are present, when I increase the dose accordingly, giving grape juice, 1-3 ounces once or twice a day 48 hours after I begin my treatment on both pneumonia and tuberculosis patients. Care should be exercised with grape juice lest idiosyncracies or physiological factors interfere with an excess of the use of same. Food, as already suggested, is pushed with cranberries and apples, etc., for variety and therapeutic reasons. Food is not only desired but well tolerated, and the family, friends, and patient are all happily provided for and cease to worry lest the patient will not receive enough nourishment.

I have personally treated, successfully, over one hundred cases—with two deaths—of the various types included in this series. I have had nephritic, tuberculous, alcoholic, influenzal, postoperative, and frank lobar pneumonia of pneumococcic origin—and here, with pride, I add the acid test of success of this therapy was the complete recovery of a child of four and one-half years of age with anterior poliomyelitis with a double basal lobar pneumonia. The ages of these patients have varied from six months to eighty-two years.

PAN-PEMMICAN.

A PRIMITIVE RATION ADAPTED TO MODERN NEEDS.*

BY GEORGE HOMAN, M.D.,

ST. LOUIS.

A STUDY of the practices of aboriginal peoples, living close to nature with respect to the instinctive manner of their dealing day by day with the problems of living may often afford important hints to those who abide in more pretentious stages of progress, and serve to remind the latter that the laws of organic nature still hold sway, howsoever much civilization may have outwardly affected conditions amidst which such lives are spent.

The fundamentals of human feeding must always remain sustantially the same; and a glance therefore at the eating habits of the early tribes on this continent may not be without interest.

The American Red Indian was chiefly a flesh-eater, drawing food supplies principally from the yield of the chase and fishing. It was in the case of the larger tribes only, with relatively stable conditions of residence, that tillage of the soil for grain production was resorted to and the crop usually was maize or corn. The milling of grain was laborious hand work, and this sort of food supply seemed to be never over-abundant. When the planted crop failed and game animals and fowl became scarce famine was a common experience with such tribes.

When the braves took to the warpath they carried with them a ration consisting of dried venison beaten to a pulp, which was combined with certain wild berries or fruits; animal fat was added and the whole then pressed into the form of cakes.

This food product was called pemmican by the Indians, the term being adopted by the whites, and was a compact and nutritious form of food especially suited to meet the physical strain of strenuous effort on hostile raids and warlike forays.

When the pioneer white settlers found conditions on the frontiers sufficiently stable to permit of safe farmwork the principal grain crop planted was corn; and it would appear that to the Indian pemmican they added parched corn reduced by pounding or grinding to a coarse meal; and thus created a kind of aliment that fully met all the demands of the body, being in concentrated form, inviting in flavor and aroma, appetizing, and digestible.

It has often been a reason for wonderment that this valuable and comparatively inexpensive form of food has been so completely lost sight of, especially during the last few years, and since the prices of everything that goes upon the table have reached such forbidding heights; and the subject is brought forward at this time in the hope that by some such recourse the cost of wholesome living will be substantially lessened to many worthy persons who now severely feel the pinch of high prices.

The name attached to this resuscitated culinary product while not strictly classical yet leans that way by reason of having borrowed from the Latin word *panis* the first syllable in order to signify the union therein of bread-stuff and meat-stuff elements, together with dried chopped fruits and seasoning to increase its acceptability to the digestive powers.

*Read at a meeting of the Staff of the Free Dispensary, Parish of the Holy Communion, St. Louis, June 7, 1920.

The measurement of food values by means of calories estimation may in fact prove quite fallacious, even when they appear correct, for the reason that certain dishes, though scientifically and technically approved, may yet be presented in such manner that the senses concerned will be offended; the proof, therefore, of pan-pemmican is in the eating; and this, when properly prepared and served, is palatable and satisfying in an eminent degree, while the cost can be kept down to a low market level.

If fresh meat is used, cuts of lean beef from shank or flank, free from fat, are preferable, while the cooking process should be very slow and of a penetrating nature. In aboriginal usage the lean venison, which is finer in fiber and flavor than beef, was dried in strips, presumably by smoking, and was somewhat analogous to our own dried beef, to the jerked beef of South America, and the biltong of South Africa.

If the poet spoke truly of Peeping Tom of Coventry, that "Heaven cancels a sense misused," then it may also be true that nature annuls a power or function unused, on the principle, perhaps, that if no work is given to the teeth there is no need for them; and this fact in modern life among white people touching dental conditions must plainly appear to those who can see things as they are among town populations. Children past their earlier years are usually fed on dishes of mush or slush, porridge, pudding, etc., and almost nothing is given to them on which by the grinding action of jaws and teeth these important parts can be exercised and normally developed; for by such exercise only can wholesome conditions of gums and teeth be established, nerve and blood supply maintained, and resistance to decay strengthened.

The addition of parched corn coarsely ground to pemmican supplies a most palatable inducement to chewing performances, which are equally enjoyable and necessary for the proper mingling of the saliva with the food intake. The changes in the maize kernel, brought about by the proper use of heat, are interesting in their chemistry, and all tend in the direction of more perfect digestion and better nutrition. The tough covering of the grain is rendered friable, and in its dietary effect overcomes tendencies to constipation. The raw starches are transformed into more easily digestible elements (dextrose, maltose, sucrose) affording an agreeable savor which stimulates stomach action; while the oil in the kernel is changed to a volatile state that yields an inviting aroma. The applied heat turns the contained moisture into vapor which distends the grain and favors all the changes above briefly indicated.

The inclusion of fruits or berries in pemmican was a notable instance of obedience to a craving decreed by physiologic law in the animal economy for the prevention of scurvy, and that the Indian had his reward cannot be doubted; for, at about the same time, English fleets, both naval and commercial, were sometimes paralyzed in operation, with heavy loss of life among their crews, by the presence of that disease. Hospitals were crowded by wrecks of seafaring men, who had lost all their teeth by scurvy;† for it took a long time for the

†The former seriousness of scurvy as a menace to the success of military operations in the case of land forces, as well as seamen, is well shown by the expe-

simple truth that lime juice would prevent that disability to get through the skulls of those in authority; but when finally such an allowance, or its equivalent, was added to the ship ration the disease became almost an unknown quantity.

It is supposed that wild plums, cranberries, and other tart forms of fruit were the ingredients of pemmican as originally made, and that wild honey or maple syrup was added to give adhesiveness to the mass, and which also was an important element of nutrition in this admirable preparation for human feeding. To-day the choice of fruits for pan-pemmican would probably be finely chopped dried cherries, currants, prunes, raisins and the like, although the dietetic need for such inclusion is not now what is was in pioneer times, but the tempting savor afforded by their presence cannot be overlooked. Again, there would be no present need for adding fat to the preparation, as the whole-milk supplied to its little patrons by the Dispensary would in its fat-content meet the due demand in that direction.

If this form of feeding should be adopted by the Parish Dispensary service, as affording a maximum food value at minimum cost, it is suggested that with suitable oversight it could be conducted with no financial outlay other than the cash paid for market supplies. For example, half-grown boys and girls no doubt would volunteer for this service, the parching and grinding of the grain being assigned to the boys, while the girls would handle the meat and fruit portion. Not an atom should be wasted, for if bones are received with the beef these when cleared of the meat should be given to the boys, who with hammer or saw would reduce them to small particles. These, when slowly simmered in water, would give up all of their organic matter and some of the mineral salts, and the resulting liquor would make a valuable soup-stock. Even the remaining fragments of bone have a market value in the form of meal with raisers of poultry for egg production.

Very much more could be said on this subject, for it touches the very foundations of physical vigor and life. The unhappy parade of painted faces seen on the street—too often hard, stunted and uncomely in expression—appearing above bodies that do not seem to be old in years, bespeaks a deep-lying cause operating at the basis of vitality and which moral or social influences cannot adequately explain. The causes responsible for such general lack of wholesome bodily conditions must have been in silent, secret operation for years, and their sinister effect is seen in scurvy conditions that the younger generation seeks to hide with masks of paint and powder.

For these conditions the elder generation of housewives and home-makers must be held chiefly responsible; for, within the years known to all now present, under pressure of economic and other causes, the patronage of public eating places has been vastly increased, the character and quality of such catering has been fundamentally changed for the worse without recognition by the public of the fact; beguiled by false appearances such patrons have lived in what in effect is a fool's paradise, and as Nature's law is inexorable the penalty of transgression must be paid. The people perish for lack of knowledge of wholesome food preparation—bastard baking, counterfeit cooking, misfit or pernicious kitchen service must, in impartial judgment, be held accountable for the malnutrition now everywhere visible among the population.

The hope of sages of earlier times was for a sound mind in a sound body, and this end was sought by study of, and obedience to, natural law; and it would be entirely reasonable to expect that a sound soul would complete this trinity of blessings, for such a result would in fact be pure religion and undefiled, as natural to man as the air he breathes.

Effective action for the betterment of such conditions as have been sketched of necessity must hinge largely on the disposition of those in official station; but, unhappily, such authority in this community with reference to the issue raised seems to be as slothful and unseeing as was the naval board when English fleets were being decimnated in manpower by scurvy—only by endless prodding and protest could relief be secured.

What has been offered on this occasion has not been primarily to move to such action; but rather, with reference to the young lives coming within range of the influences of this institution, that they should enjoy a better nutrition by the means suggested, and gain at the same time a fair knowledge of natural law in bodily growth, digestive action and the why and wherefore of the processes employed in wholesome food preparation.

The almost universal form of food called bread which, when prepared from good materials in right proportion and properly baked, is correctly enough spoken of as the staff of life, has been turned rather into a club of death by local ignorance and indifference and commercial greed and craft—a double swindle affecting both health and purse being perpetrated on the users of such sinister products through what appears to be corrupt collusion on the part of manufacturer and caterer.

Efforts directed in opposition to such a regime of sloth and piracy do not seem promising; for, so long as housekeepers and bread-buyers are content to be gulled in such fashion and tamely submit to rank imposition they deserve to suffer all the ills that flow from such manifest delinquencies.

The plea made here and now is chiefly in behalf of a younger generation, the hope being that through influences brought to bear possibly through

---

rience of the expedition sent out by the French Government in aid of the American Colonies against Great Britain, under the command of Comte de Rochambeau. This enterprise was very popular with all classes of the French people, and special care was taken to insure success. From among a great number who offered themselves for service, only the physically fit were selected. The troops numbered 6,000 men, and the Fleet sailed from Brest May 2, 1780, reaching Newport, R. I. on July 7 following. A few days later the commander of this force officially reported to the French Ministry of War: "And the scurvy has ravaged our army"; (Merlant) "1,500 of my men sick on the ships, 800 in the army"—this in the case of a thoroughly provided fleet, as considered at that time, and in the pleasantest season of the year. Further, the noted Russian commander in the Napoleonic wars, Suvoref, reported as follows: "There is no scurvy in Finland. . . . By means of cabbage, tobacco, and horseradish scurvy has been stopped, and by cleanliness, too." (Blease).

this and like places, they may grow up to better things unburdened in body and mind by ills that are avoidable, fitted to deal in wholesome fashion with all the problems that may come to them in life, and to this end practice and precept, sound and sane, as briefly suggested herein, must ever play no inconsiderable part.

NOTE.—The excellent keeping quality of the alimentary preparation suggested above happened to be proved in a manner entirely accidental. A copy of this paper reached two accomplished nurses, cooks and dietitians on the Pacific Coast, who at once proceeded to the production of Pan-pemmican on the line suggested. A sample of this product was received by the writer (in St. Louis) and at once distributed as widely as possible among children, by whom it seemed to be much relished. By an oversight one cake was mislaid and lay, loosely wrapped and in common room temperature, from July, 1920, to the February following, when it was discovered and found to be entirely free from mould, fermentation or souring; though very dry it was in fact as palatable as the day it was made.

716 CENTURY BUILDING

A BRIEF DISCUSSION ON THE POSSIBLE RÔLE OF THE THYMUS IN GRAVES' DISEASE AND IN MYXEDEMA.

BY G. A. FRIEDMAN, M.D.,

NEW YORK.

MUCH experimental work has been done on the thymus gland, yet no evidence has been found that it furnishes a hormone. The question arises as to whether one is justified in considering the thymus as belonging to the group of endocrine glands on mere hypothetical grounds. Such hypothesis does not seem tenable at first glance, because it is impossible to decide whether the gland should be considered as a lymphoid or an epithelial organ. Were the latter true, the hypothesis of a thymic hormone would deserve great consideration.

Stöhr,[1] for instance, states that the thymus should be considered an epithelial organ. The thymic cells, according to him, have only externally a mistakable similarity with lymphoid cells. Gierke[2] believes that finer studies of the thymic cells, and the special staining for specific granulations, may decide the question of the thymus as being an epithelial organ.

In spite of definite information as to origin, one must admit that thymic hyperplasia has been noted very frequently in Graves' disease. It is true that the presence of a large thymus in this condition can rarely be demonstrated on *x*-ray examination or by percussion, but thymic hyperplasia, as will be shown later, has frequently been found in exophthalmic goiter cases at necropsy. Because of this occurrence, some have even conceived a thymic type of exophthalmic goiter.

As an enlarged thymus is a frequent finding in those who die from Graves' disease, one would expect the histology of the thymus in this condition to rest on a solid basis. But a few remarks will serve to indicate how contradictory is the histopathology in hyperthyroid states. In a case of Mönkelberg[3] and in a case of Hansemann[4] numerous Hassall corpuscles were found in the thymus. In a case of Soupalt,[5] the increase of Hassall bodies was so enormous that the histological picture resembled a carcinomatous growth. There were no Hassall corpuscles in a second case of Hansemann and in a third case of his the enlarged thymus consisted solely of lymphatic tissue. Dirker[6] reports an increase of lymphatic tissue in a large thymus in a case of Graves' disease. Since a hyperplasia of the thymus is associated either with an increase of Hassall bodies or increase in lymphoid cells, there must be a great deal of truth in the statements of Stöhr and Gierke.

Although the function of the thymus is not understood in either normal or abnormal states, the fact remains that the enlargement is associated with an indisputable and typical endocrine disorder, *i.e.* Graves' disease. The frequent hyperplasia of the thymus in the latter condition strengthens the suspicion that the thymus is an endocrine gland.

As it is well known that there is an antagonism of symptoms between subjects afflicted with Graves' disease and those afflicted with myxedema, one would expect to find in the latter condition a hypoplasia of the thymus. It is the consensus of opinion at the present time that thymic tissue persists throughout life and never involutes completely, in the full sense of the word. By this is meant that, just as in the individual afflicted with Graves' disease, the thymic remnant leads to hyperplasia, the thymic remnant of a myxedematous individual becomes still further atrophied.

I know that many speak of a persistent thymus in Graves' disease. While Hoxie[7] denies the existence of a persistent thymus, one must agree with Halstead,[8] who has expressed the view that the thymus in Graves' disease is activated anew by the thyroid gland. Hyperplasia of the thymus may be due to other causes besides stimulation from the thyroid, as in the status thymicolymphaticus. Hoxie, I believe, is right in speaking of reactivation of the thymus from unknown causes. This author relates the following case: A young farmer, seen at the age of 19, had been suffering from shortness of breath for two years. Formerly he had been the fattest member of the family, but he was very thin when he came under Hoxie's observation. The manubrium of this patient was resected and some pieces of the thymus removed. The microscopical study of these revealed the epitheliazation described by Matti and Klose[9] as characteristic of reactivation of the adult thymus. The causes of this reactivation are unknown. His case also shows that loss in weight may be due to thymic hyperplasia.

Friedleben[10] showed that the thymus gland is not essential to life. It may be extirpated in animals without any consequences to the general welfare of the young. Pappenheimer[11] recently arrived at a similar conclusion through his experiments. The thymus, according to Friedleben, may be missing in otherwise normal fetuses and in children; yet in some pathological conditions the thymus is found to be hyperplastic or atrophic. In Friedleben's experiments one finds a suggestion as to the possible atrophy of the thymus in myxedema. There was no atrophy of the thymus found in young dogs when he resected the left vagus, but after section of the vagus, the sympathicus, lower cervical and upper dorsal ganglion of the sympathicus complete involution of the thymus occurred. Halstead[12] noted atrophy of the thymus in a myxedematous dog. Atrophy of thymus in thyroidectomized animals was

found by Hofmeister,[13] Haushalter and Jeandelize,[14] Blumreich and Jacoby,[15] and Tatum.[16] The latter author has also made the interesting observation that in rabbits the thymus atrophies after excision of the thyroid gland.

Scholz[17] states that at autopsies, the thymus of myxedematous individuals was frequently found diminished, atrophied, sclerotic, or in a state of interstitial inflammation. It is also true that in some cases the thymus was found large and persisting in old age, but it must not be forgotten that a gland may be large and degenerated at the same time. It was explained in a recent article,[1] that the large hypophysis in thyroidectomized animals and the large hypophysis found at autopsies in myedematous individuals, may be of a degenerative nature, while the nonenlarged hypophysis in Graves' disease is practically a physiological hypertrophy. The same may be possible for the thymus. Von Harberer[19] reported a case of Graves' disease in an individual who was operated upon by Kocher. The patient did not improve; but after thymectomy he became perfectly well. Instead of the expected large thymus gland only a very small one was found, and in this thymic remnant numerous Hassall bodies were located.

It may be of interest to note that in myxedema the assumption of a hyperfunction of the adrenal cortex, as explained in a previous article,[20] is in accord with a hypofunction of the thymus. Brugsch[21] writes that injections of adrenal cortex produced a diminution of the thymus with regressive phenomena.

May it not be possible then that some symptoms and signs of Graves' disease are partly due to hyperplasia of the thymus, and the same of myxedma to hypoplasia of this gland? The increased metabolism in Graves' disease may partly be due to thymic hyperplasia; the decreased metabolism in myxedema to a hypoplasia of the thymic remnant. In the previously mentioned case of Hoxie's in which there was loss of weight, hyperplasia of the thymus was demonstrated. Brugsch[22] states that after thymectomy in young dogs, marked adiposity occurs after 14 days. In the myxedematous dog of Halstead the thymus was found to be atrophied.

It is highly probable that exophthalmos, which is one of the cardinal symptoms of Graves' disease, may be partly due to thymic hyperplasia. The statistical data of Albert Kocher[23] showed that exophthalmos was present in 70 to 80 per cent of typical cases of hyperthyroidism. The percentage of bulbar protrusion in Graves' disease corresponds closely to the incidence of thymic hyperplasia in this condition.

Rössle[24] reports a series of 52 cases of hyperthyroidism with thymic hyperplasia. McCardi[25] found 18 cases with thymic hyperplasia in 35 cases of sudden death in hyperthyroidism. Matti[26] found in the literature 183 cases of hyperthyroidism on which postmortems had been held. In 98 cases, making 74 per cent of the total number, hyperplastic thymuses were found. Thus 74 per cent. of thymic hyperplasia is a very close comparison to 70-80 per cent. exophthalmos. These figures lead one to suspect the possible rôle of the thymus as an operative agent in the causation of exophthalmos.

Omitting the various theories which have been advanced for the explanation of bulbar protrusion in Graves' disease, the consensus of opinion at present seems to favor the theory of cervical sympathetic stimulation. This stimulation in man is supposed to be brought about by the excessive secretion of thyroid products. But the effect of this stimulation is absent in 20-30 per cent of typical hyperthyroid cases. May not the reason for the absence of exophthalmos in these cases be the simultaneous absence of thymic hyperplasia?

The assumption of the cooperative work of the thymus as causation of exophthalmos is quite in accord with some experiments. Bircher[27] experimentally produced in dogs, tachycardia, nervousness, tremor and exophthalmos, by injecting thymus products into the peritoneal cavity. Crotti[28] repeatedly found these symptoms developed moderately after thymus injections. The antagonistic symptoms of narrowing of the eyelids, or enophthalmos, frequently met with in myxedema, may also be due to hypoplasia of the thymus aside from thyroid insufficiency. In Friedleben's experiments, after section of the sympathicus, atrophy of the thymus developed. By analogy, atrophy of the thymic remnant, as found in myxedema, may inhibit the cervical sympathetic.

From the considerations developed in this paper it follows that, although a thymic hormone has not yet been demonstrated, the thymus shows changes in two typical endocrine disorders: Graves' disease and myxedema. The hyperplasia in the former may be partly responsible for the increased metabolism and for the causation of exophthalmos; the hypoplasia in the latter for the decreased metabolism and the causation of enophthalmos.

Thymus, therefore, should be contraindicated in the hyperthyroid states and added to thyroid extract in the treatment of subthyroid conditions.

1000 PARK AVENUE.

THE STANDARDIZATION OF HOSPITAL TECHNIQUE.*

BY JEROME SELINGER, M.D.,

NEW YORK.

INSTRUCTOR IN SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE standardization of anything—whether it be hospital technique or a wage scale—is not a new theory. But in these present years of scarcity, inefficiency, confusion and continually mounting prices a revision of our older methods, incorporating some new ideas, should not be amiss. Most hospitals are poor. The income derived from investments, plus an allowance from the department of charities for taking care of the poor, is rarely, if ever, sufficient to meet expenses. The deficit, therefore, must be supplied by a generous benefactor. In the past such benefactors have been available. But at present with the heavy demands "to give" upon our people of wealth, together with the luxury tax, the excess profits tax, the income tax, and what not, it is questionable if any money will be left for the support of mere hospitals.

The money aspect, while important, is not the only question to be considered. A lessened dispensation of energy with an equal amount of work, or more; a clearer understanding of what to do and when to do it; a better and more thorough training for our interne and nursing staffs would primarily result from standardization. By standardization I do not mean to imply one man rule. There is nothing so detrimental to the advancement of science as a hospital dictator. Any institution suffering from the effects of a boss is bound to reflect the personality of its particular boss. Such a situation is, in a vast majority of cases, morally depressing. The institution and all that it stands for must consequently suffer.

In private sanatoriums and smaller hospitals there is an unconscious and unintentional systematization and standardization of technique. This arises from the fact that no large gifts of money ever find their way to institutions of this type. The owner of a sanatorium will try to furnish whatever is demanded of him by the majority of physicians and surgeons who support his institution. This majority may not demand the articles that are generally accepted as the best, but since they do most of the work and therefore use most of the material at the sanatorium, it is logical and just that their wants should be satisfied. The owner consequently limits his purchases so that they may conform to the requirements of the majority. The minority must alter their method, bring their own material, or take their work elsewhere. While this is a method of standardization—automatic standardization—it is not necessarily the best method.

It is, however, chiefly of the larger and more complex hospitals that I wish to speak; those with several surgical divisions as well as divisions for surgical specialties; those that teach undergraduate as well as post-graduate students; and those that do not teach at all. It is in hospitals of these types, where the service is large and flabby, where, because of their size, proper supervision of details becomes impossible, where each individual operator is a law unto himself, where technique and ethics are lost in the mad rush for success,—it is in these hospitals that valuable time, expensive material, and precious money are lost by the wholesale.

It has been said "When men smile and agree, progress ceases." Generally and scientifically speaking, there is absolute truth in the statement. For that reason individuality, research, the development of new ideas, should be encouraged in every possible way. To the casual reader and superficial thinker it might appear that individuality and standardization were incompatible. That is by no means the case, as I shall attempt to prove.

Let us consider a hospital with twenty operating surgeons scattered throughout the various divisions. Doctor A. prescribes three drams of licorice powder for a preoperative cathartic; Doctors B. and C. give castor oil and Hinkle's pills respectively in similar cases; Doctor D. orders morphine for a preoperative sedative; Doctor E. gives morphine and atropine, while Doctor F. prefers scopolamine. Doctor A. uses laparotomy pads to protect the wound edges, but Doctors B. and C. have not time to bother with such technique. The same system of variation occurs throughout the operation and continues in a more marked degree during the postoperative treatment. The variations in postoperative treatment are so marked as to warrant special mention. Doctor A.'s patients without apparent reason are dressed on the first day following an operation and they continue to be dressed every two or three days until the seventh, eighth, ninth, tenth, eleventh, or twelfth day, when the sutures are finally removed. Some of Doctor B.'s patients receive their primary dressing on the seventh or eighth day after operation regardless of the fact that one of them may have a markedly elevated temperature. As a postoperative narcotic Doctors A., B., and C. give one-quarter, one-fifth, or one-sixth of a grain of morphine, respectively. One could cover many pages with the great variety and number of discrepancies which occur in the general technique of a single institution. But I think I have cited a sufficient number to clarify the evil and make it evident that our only salvation lies in systematization.†

* From the Surgical Department of Dr. Chas. Gordon Heyd. Paper read before the Junior Faculty Association of the New York Post Graduate Medical School & Hospital May 25, 1921.

† I have in mind an institution that has a fourteen-page "Standing order book." Each attending physician and surgeon has his own pet orders listed, and no two of them are alike.

With the above statements in mind, it is not difficult to realize the multiplication of work for the doctors, nurses, and all hospital attendants. The work of each individual is increased and therefore the work of the entire machine is increased. And the expense account of the hospital is increased in direct proportion to the number of revolutions of the machine. Catgut and other suture material, gauze, iodine, alcohol, adhesive plaster, etc., etc., are expensive. The wear and tear on surgical instruments is not negligible. The life of a hospital towel or sheet is, at its best, not too long. The waste, therefore, the unnecessary waste, would be found to be stupendous if computed.

Without destroying individuality, without making one surgeon a slave to another's technique, without destroying initiative and the incentive to new ideas, how can we curtail waste and extravagance and permit the credit and debit side of a hospital ledger to approximate each other? The answer is "standardization of technique," a liberalized standardization, adoption of a standard that has been scientifically proved to be surgically sound in all of its angles. For example, if the leading surgeons to-day use chromic catgut for the suture lines in a gastroenterostomy; if pathological examination eliminates catgut as a cause of ulcer at the site of a gastroenterostomy; and if a like examination proves that silk or linen thread may be a cause of such ulcers, then why should any surgeon (in a controlled institution) be allowed to use linen or silk in doing a gastroenterostomy? If, once again, the accepted practice of a majority of surgeons is to dress a wound on the seventh, eighth, or ninth day, provided, of course, there is no reason to suspect an infection, why, in hospitals of repute, are men allowed to dress it on the day following an operation and on each second day thereafter until the sutures are finally removed? Why are hospital internes permitted to probe a wound? Why, one might ask, do the hospital authorities allow a probe on the dressing tray? It is not difficult, with these few examples in mind, to realize the multiplication of work and the immense waste of material resulting from varieties of technique.

What are we going to do about it? Whose technique and whose teachings shall be adopted? Shall we accept the methods of Doctor A. because he does most of the work at the hospital? Or Doctor B. because he is of the new school? Or Doctor C. because we personally like his methods? By no means should the practices of any one of these men be accepted and followed. The self-evident course is the one to be pursued. The technique of the majority of doctors—or the technique of any one doctor—*when scientifically proved to be the best*—should be accepted as the hospital routine. It should stand as the best, it should be rigidly adhered to until another method has been proved to be superior. It should not be difficult to adopt this procedure. Every first-class hospital has its associated laboratories where pathological and bacteriological examinations can be made. Every new idea or theory as to technique—whether it be preoperative, operative, or postoperative—can be submitted to a surgical committee who will appoint a certain number of operative surgeons thoroughly to test the proposed change. The results obtained should be outlined in the form of a report and referred to the surgical committee for consideration. If the report is favorable and the new method proved to be better than the old, then it should be established as a part of the hospital routine, supplanting the older method.

Every surgeon strives for the best results. They are all desirous of using the best and most generally accepted technique. So, after all, a standardization of hospital technique is merely a localization of an already accepted general standardization. Each hospital will do its own pathfinding, the essential point being that all the surgeons should follow the pathfinders until a better way has been shown. This will in no way curtail initiative, and no one's ideas or theories will be cast aside without a fair test.

A detailed outline and list of the saving thus effected are certainly not necessary. It is not difficult to visualize the systematized smoothness with which a hospital so standardized will run. A smoothly running machine needs little attention, and excess help can therefore gradually be dropped. An interne staff, when taught to work systematically, will be able to handle a greater volume of work and its number can be decreased. With fewer details and a standard method of bedside nursing, the nursing staff will become more efficient. Student nurses will then be able to do the work that now requires the services of a paid graduate. Aside from the better service thus afforded, hospital expenses will be tremendously reduced, and a part, at least, of the gift money, will be available for research laboratories and an increase in bed capacity.

THREE CASES OF CENTRAL SPEECH DEFECT.

By N. J. Poock van Baggen

San Francisco, Cal.

In the record which I kept for seventeen years of the diseases of speech, attended to mostly in my institution at The Hague, Holland, I classified the cases in the following three groups:

1. The peripheric-impressive, or perceptible defects (in which the organ itself, or the nerve fibers which bring the impressions from without to the centers of speech, are destroyed or in a morbid condition).

2. The central speech defects (in which the sensorial centers, or the motor centers, or the fibers associating these centers are affected). Of this group we distinguished again: (*a*) Central speech defects *with* anatomically perceptible alterations in the brains, and (*b*) Central speech defects *without* anatomically perceptible alterations of the brains.

3. The peripheric-expressive, or articular speech defects (which result from a disturbance in the motor fibers which unite the motor centers of speech with the muscles, or from a trouble in the articular muscles themselves).

When I look over this record I find that the greatest number of the cases were peripheric-expressive defects of speech.

The peripheric-impressive defects, excluding the congenital deaf mutes, which form a class by themselves, are represented by few cases. Also, the

central speech defects *with* anatomically perceptible alterations are not numerous, while on the contrary the cases of central speech defects *without* anatomically perceptible alterations occurred very frequently. Under this last group we classify the stutterers, hence, this great number; and, indeed, going over this last section of my record it shows almost nothing but stutterers and only very rarely a few other cases. From the aspect of the disease itself, its cause and its progress, however, those few cases are most interesting, and this induces me to report three of them here. Two of these belong without any doubt in the last-named class, while, with regard to the third, we hesitate to place it either in the class of the central defects *with* anatomically perceptible alterations, or in that of the central defects *without* anatomically perceptible alterations. However, as my reasons for placing this third case in the latter class were prevalent I decided to leave it there for the present. One of these cases was attended to a few years ago in my institution at The Hague, Holland; the other two occurred but recently at the clinic of the Stanford University Hospital at San Francisco.

CASE I.—A young man of not yet 17 years, came to me shortly after having passed his examination of admission to the University of Leyden. He obtained his admission only under the condition that he would take a thorough treatment for his speech impediment. Examination of the patient's speech showed the following state of things:

When speaking he intermingles the words of the sentences, which, however, are uttered fluently. He says: "I good results passed with my examination," instead of "I passed my examination with good results." "This morning I on bicycle Scheveningen went tennis to with friends my play," instead of "This morning I went on my bicycle to Scheveningen to play tennis with my friends." (Of course, the patient used the Dutch language; I try to report the mistakes as nearly equivalent as possible in English.) It is most remarkable that the patient himself notices his mistakes only when, not being understood, he is requested to express himself more plainly. Then, trying hard, and paying close attention, he sometimes succeeds in pronouncing a few correct sentences, when it happens to be not too complicated an utterance. In school, when he had to make a statement of some extent, and on a difficult subject, he managed, by paying close attention, to produce a few not correct but still intelligible sentences. The slightest interruption by the teacher, however, was enough to make him so nervous that he lost all control and got quite entangled in his words.

Reading aloud also causes much difficulty. He will pick up a word of the line above or under that which he is reading and insert it in that line; or he will skip words and interpolate others which are not in the text. In this instance, also, only when attention is called to his mistake he is aware of it. He understands perfectly what he is reading, while it is impossible for others to understand it.

Writing causes no difficulty at all; on the contrary, the patient shows a great ability in expressing his thoughts by writing, and his composition is of excellent construction. This explains how he passed his examinations with good results. He is very intelligent and talented above the normal, which made him a special favorite with his teachers, and so he was allowed to write his answers down most of the time and also during his examination.

His general condition is good, he makes the impression of a sturdy young fellow. He is a great tennis player. Only latterly he was becoming morose and withdrew more and more from his companions, because of his difficulty in expressing himself.

As a baby he was slow in learning to speak and even when six years old expressed himself in baby-talk. In infancy he had no sicknesses other than a mild attack of measles. Complaints of his speech came only when he went to school and began to read. However, he got along and seemed to get over his trouble until between his thirteenth and fourteenth years when there came a change for the worse and from then on he began really to suffer from his speech defect. Unfavorable circumstances (divorce of parents) were the reason that nothing was done to remedy the evil.

As the patient is able to speak and even to speak correctly, although it be but a few sentences, he gives the impression of a case of aphasia, not located in the centers themselves, but having its seat in the fibers of association which unite the different centers of speech, thus producing paraphasia; and I concluded it to be an inharmonious development of this association, hence the intermingling of the words. The fact that many times the patient does not notice his mistakes must be explained, I believe, by his giving all of his attention to his subject and not to how he expresses it. Very many do this, but when the speech apparatus works normally there are no unfavorable consequences. In comparison with his well-developed muscular system, the muscles of the tongue and lips show weakness, which must be considered as a result of the irregularity.

For the treatment, we began to submit the patient to the regular speech and voice hygienics, having in view the general strengthening of the muscles and at the same time to obtain a more conscious control over the speech. During the first week the patient was told to limit his speaking, outside of the daily treatment, to the strictly necessary, and to do his utmost to pronounce those few sentences correctly. Besides the articular, breathing and voice exercises, he was asked to repeat slowly, but very distinctly, short, easy sentences, which I wrote down. Sometimes, at the beginning, even this repeating caused great difficulty. It was never extended for more than ten minutes. After this the sentences that had been pronounced correctly were read aloud. By and by the sentences were made longer and more complicated. Then, instead of one sentence, I pronounced two at a time, then three, and so on, which led us at last to the repeating of a small story. Short poems with a marked rhythm then proved to be of great help.

In the second week the patient was told to speak a little more, but only to members of his family or to friends who were familiar with his trouble.

In the third week of the treatment, instead of repeating sentences, the patient had to answer questions. Those questions were put in such a way that the answers became more and more complicated.

While the speaking improved steadily without interruption the reading caused much more difficulty and it was only in the fourth week of the treatment that the patient succeeded in reading a small piece without preceding preparation.

The treatment lasted altogether six weeks. In the last week, to put the patient to the test, he was requested to give short lectures on different subjects. For some of them time was given for preparation. The last was an unprepared improvisation on a book recently read. Then, as there appeared no more of the old trouble, the patient was dismissed. I requested him, however, to come in as soon as the slightest difficulty might reappear. When he did return it was only to tell me that he had commenced his studies at the University and that he had no more trouble whatever and felt perfectly at his ease concerning his speech.

The cure of this case was not difficult in so far as it consisted only in adjusting the equilibrium of an otherwise perfectly healthy individual.

CASE II.—This was a middle-aged man, 36 years old, well-educated, by occupation a salesman. In July, 1920, the patient lost his speech suddenly while on a trip. He could not tell the conductor where he wanted to go and was unable to utter a word. He had full knowledge of everything and understood everything spoken to him, only felt dizzy. On the same day he noticed that he had not the entire use of his right arm, nor of his right leg. Swallowing also became difficult and he was much troubled by saliva. This state of things continued for about six weeks, then all at once he found

himself saying to his children: "Leave that dog alone." After that he was able to say more things. Answering questions then proved to be easier than posing them or than making a statement. He had trouble in forming ideas and when he began to put them into words he was often unable to finish the sentence. At the same time as his speech gradually came back, the paralysis of the arms and legs ameliorated.

On August 23, 1920, the patient entered Stanford University Medical Hospital at San Francisco (No. 87573) where his case was stated to be one of cerebrospinal syphilis, and he underwent Dr. Mehrtens' special treatment for this disease, with the most satisfactory results. (An extensive history of this case is registered in the records of the hospital.)

On November 22, the patient was able to repeat only 34 words in three minutes. He was placed under special treatment for his speech on January 25, 1921. The complaint at that time was that he could not yet speak fast enough (63 words in three minutes) nor could he remember what he wanted to say. Being a salesman he had special difficulty in remembering his "sales-talk." He not only could not find his words, but also mixed up the words, mistaking one for another. His speech was indistinct, owing to heaviness and clumsiness of the articular muscles. Given a test of the pronunciation of each vowel and consonant separately, it appeared that none was missing and that vowels as well as consonants were all correctly formed. The sensorial speech, that is the understanding of speech, was unaffected. The patient could repeat all words, even the most difficult, and answered correctly all kinds of questions.

The case gave the impression of being one of motor aphasia without anatomically perceptible alterations of the brain, combined with paraphasia, resulting from the cerebrospinal syphilis. His not being able to remember and to speak words indicated motor aphasia, while the intermingling of the words and the mixing up of the expressions showed paraphasia, that is to say the association between the different centers of speech was affected.

For the treatment the patient was given a series of breathing, vocal, and articular exercises, especially the last-named, having in view the amelioration of the heaviness and clumsiness of the speech, while, at the same time, these exercises were of great benefit for the control of the speech. At each session he was requested to name a series of objects, either from his surroundings or from pictures, trying each time to increase the number of words. Small poems were given to memorize. To combat the paraphasia, rhythmic exercises were given, composed of syllables, first with the easiest consonants, later with more and more difficult combinations of consonants and vowels. Also, sentences were given, at first short ones with easy combinations of words, and when these were spoken faultlessly from memory, more complicated word combinations were chosen. These exercises proved to have an excellent effect, especially as regards the intermingling of terms. The patient, realizing the benefit they gave him, took a regular fancy to these sentences and found great pleasure in practising and memorizing all kinds of tongue-twisters. This favorable disposition of the patient and his energy and perseverance contributed not a little to his recovery. We can indicate the means and lead the way, but in most cases the essential, the very core of the success of the treatment, lies with the patient himself, in his character, his conception of and his affinity for the treatment.

CASE III.—This was a young man, 20 years old, who lost his speech in an attack of lethargic encephalitis, from which he suffered from October 23 to November 26, 1919.

My first interview with the patient took place at the beginning of March, 1921, in the neurological clinic of the Stanford University Hospital, when the state of things appeared to me as follows: Patient cannot utter a word for several minutes, then, at last, in answer to a question, he produces a few words in a low, monotonous, somewhat husky voice. Evidently it costs him a great effort to pronounce those few words. With each following question the answer comes in the same slow, reluctant, incomplete way. In his effort to speak the patient is much bothered by saliva; before he finally begins to speak he swallows repeatedly. The articulation is correct, but weak and lacks distinctness; the consonants are somewhat run together, as is often the case when the innervation is not strong enough. The articular movements, that is, the opening of the mouth, the moving of the lips, the protruding of the tongue, and the raising of the soft palate, are correct, but incomplete; and when the patient is requested to make a more complete movement, it appears that he is unable to do so without the movement becoming spasmodic. The movement of the tongue is often accompanied by a fibrillary tremor. The action of the pharyngeal and of the laryngeal muscles also is correct, but incomplete, which causes a slight nasality.

Physically the patient appeared to be a well-nourished, well-built, and well-muscled young man. His gait was decidedly impaired and rather unsteady; the right leg especially responding only reluctantly to his efforts. At times there was an involuntary movement in the right forearm. When the patient made a great effort to speak, this movement of the right forearm increased and he was obliged to hold it with his left hand.

The sentences spoken were often unfinished, because of the inability of the patient to utter all the words; however, the syntax of those sentences was always faultless. The patient was of normal intelligence, had gone through High School and possessed a fair knowledge of the English language. The vocabulary had remained intact; also the power of understanding words and sentences was unimpaired. This latter test was greatly facilitated by the fact that the patient was able to write, although the handwriting was not very good, owing to the disablement of the right arm.

To a certain extent it was easy to reach a conclusion in this case. All the symptoms were present which characterize subcortical motor aphasia, or the so-called aphasia of Broca, due to a lesion located in the third left frontal gyrus, and by which the power of speech is totally destroyed, or seriously impaired, while the understanding of the spoken word, as well as the ability to write, are unaffected.

It was more difficult to decide in which group this case had to be included, whether in the group of motor aphasia *with* anatomically perceptible alterations, or in that *without* anatomically perceptible alterations.

The autopsy in cases of lethargic encephalitis has disclosed numerous small hemorrhages in the substance of the brain. If that is the fact, there has been lesion and our case belongs in the first group. There is a possibility, however, that these hemorrhages are not primary, but secondary. It is certain that the symptoms observed in this case do not show the characteristics of a lesion. When there is a lesion the vocabulary is affected; sometimes the simplest words are missing, sometimes names, figures, or dates, but some part of the vocabulary is always wanting. In this case the vocabulary is intact and it appears to me that the speech inhibition is caused by a state of lethargy, or torpor, with subsequent debilitation and atrophy of the centers in question.

While in the case of motor aphasia caused by lesion, the treatment consists in reeducation, or, more exactly, rebuilding, we had here to revive, to stimulate, and to strengthen, and consequently the treatment was given with this aim in view. The patient was submitted to breathing, vocal, and articular exercises, having in view not only the developing of the muscular power of the motor, vibrating, and forming elements of speech, but also the invigorating of the nerves and their stimuli, that is, of the centers themselves. Also, various exercises were given to rouse the spontaneous speech from its languor. In these latter exercises, especially, we met with many and great difficulties. At the beginning of the treatment days passed when the patient, even with the greatest effort, could not utter more than two or three words. Slowly, however, very slowly, the improvement came and when, after four months of exercising, we looked over our daily reports, we found that gradually the bad days gave place to better, fairly good, and very good. The treatment was greatly supported by the intelligence and energy of the patient and his usually cheerful disposition. Besides the attention given to the power of speech, the patient was advised to exercise his limbs regularly and more particularly the right leg and right hand and arm.

To give a definite opinion in regard to the prognosis in this case is out of the question. The improvement gained, however slight, supports the hypothesis as to the nature of the ailment and encourages us to continue in the same course. I have in my practice encountered one case of motor aphasia, where a fairly good spontaneous speech was obtained only after three years exercising. In that case, however, the cause was different. At present it is not known what causes lethargic encephalitis, and where the causes are unknown it is very difficult to give an opinion as to the possible results.

Liebes Building,
177 Post Street.

SIMPLE METHOD OF IRRIGATING THE ANTERIOR URETHRA.

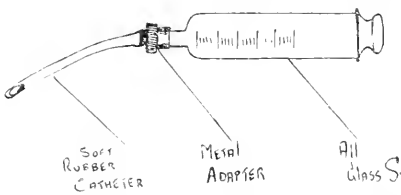
By Maximilian M. Nemser, M.D.,

New York,

Clinical Assistant, Department of Urology, New York Postgraduate Medical School and Hospital.

The present-day consensus of opinion seems to be against the irrigation, injection, or instrumentation of the posterior urethra in cases of simple anterior urethritis. It certainly would seem to be a safer procedure to confine local therapy to the site directly involved. At the same time it is desirable that the therapy be thorough.

The choice lies between irrigating or injecting the anterior urethra. The former is usually accomplished by means of the time-honored irrigating stand and nozzle, gravity being the motivating force to the fluid. The latter (injection) by means of a hand syringe.



The objections to the irrigating are that the apparatus is unwieldy and that the stream is not at all times under the full control of the operator and that it is often too forceful. As to the injection we find that the patient very often uses either too much or too little force. Another point to bear in mind is the fact that once the anterior urethra is full it no longer lends itself to lavage. It was to overcome these various drawbacks that the writer devised the following simple method:

The necessary apparatus consists of the distal 12 cm. of a 14F soft rubber catheter, an adapter, and a Luer glass syringe. The sterile catheter with the adapter attached is introduced into the urethra. The sterile syringe is next filled with the irrigating fluid and attached to the adapter and slowly emptied. The fluid easily escapes along the sides of the catheter. One or more syringefuls may be necessary to wash out the anterior urethra thoroughly. During the injection of the last 8 c.c. (The average capacity of the anterior urethra) it is well to withdraw the catheter slowly, thus leaving the urethra filled with the fluid.

With a very small meatus, a still smaller catheter may be used, or in selected cases a meatotomy may be performed. Care must be taken to inject the fluid slowly in order that it does not spurt on leaving the meatus. A 20, 30, or 50 c.c. syringe may be used. The length of the catheter is such that even when introduced to its full length it cannot pass the cut-off muscle—at any rate the operator can easily tell when the end of the anterior urethra has been reached.

The writer finds that quicker results may be obtained in these cases by instituting treatment early and that it is peculiarly adapted for a case tending to become chronic. A possible objection is the fact that one such irrigation a day is necessary—a condition that some patients may find it hard to comply with.

56 East 87th Street

Medicolegal Notes.

Hearsay Evidence as to Duration of Disease Inadmissible.—In an action on a life policy the defense was fraudulent representations by the insured in reference to his health and treatment by a physician. The particular point of attack was that the insured had had for several years interstitial nephritis, and in his application had stated to the contrary. The defendant offered in evidence what purported to be a certificate of death, made up of a certificate of death signed by the local registrar under the South Carolina Vital Statistics Act of 1914 and a medical certificate of death signed by the physician who attended the insured in his last illness. This certificate, compound of the two certificates as stated, is such as is required by the acts and the regulations of the State Board of Health. It, or a certified copy, is admissible in evidence to establish the matters therein required to be recorded when within the knowledge of the person making the certificate. Matters not within his knowledge and plainly appearing impossible to have been within his knowledge are subject to the objection applicable to hearsay evidence. In the medical certificate the physician who was called in on November 18 and attended the insured until his death, on November 30, certified to the duration of the alleged disease, a fact which the certificate showed could not have been within his knowledge. This matter being a vital point in the controversy, it was held error to allow the physician's statement as to the duration of the disease to go to the jury. Judgment for the defendant was therefore reversed.—Williams v. Metropolitan Life Ins. Co. (S. Car.), 108 S. E., 110.

Necessary Basis for Medical Opinion as to What Is Proper Treatment.—In a malpractice case the opinion of medical men may be received in evidence as to what would be the proper treatment, but in order for such expert witnesses to have a basis for their testimony they should be informed as to what treatment was given the patient, or what the physician in attendance had failed to do.—Emerson v. Lumbermen's Hospital Ass'n, Oregon Supreme Court, 198 Pac., 231.

Authentication of Hospital Records Produced in Evidence.—In a personal injury case it was held that a physician who testified that he had no independent recollection of an operation performed on the plaintiff and who only knew the contents of the record card thereof from having recently inspected it, could not prove "what the record was." The card did not refresh his memory, for, if he ever had any connection with the operation, he had totally forgotten it. The card was not properly authenticated. The witness did not write it or identify the writer or the handwriting. He did not look it over at the time it was made to see if it was a correct statement of what occurred. He could not say that what was on the card was what he dictated at the time of the operation or that he actually dictated anything that was on the card. The writer of the record was not asked to verify it as true.—Verde Combination Copper Co. v. Reito, Arizona Supreme Court, 198 Pac., 462.

FULL-TIME PROFESSORSHIPS.

IT is a little over seven years ago that Dr. Theodore C. Janeway was called from his field of useful and productive activity in this city to take the chair of medicine at the Johns Hopkins University on a full-time basis. The University had just received a grant of $1,400,000 from the Rockefeller Foundation on condition, so it was reported, that it would adopt this Teutonic idea of teaching the science of medicine, leaving the art to be gained by experience. This was, we believe, the first time the plan was put into practice in this country, and it was regarded with approval by many, for the German idol had not yet been smashed. The MEDICAL RECORD questioned the wisdom of the innovation, believing that the obvious disadvantages of the full-time clinical professorship would far outweigh its possible advantages, and that the experiment would prove unprofitable to both teacher and student, and eventually also to the institution making it. We were properly rebuked by the engineers of this new uplift of medical education, but the MEDICAL RECORD had made its protest and was content to wait for time to test the experiment. Since then other schools, some through the stimulus of further and larger grants, have adopted the full-time plan, and the medical profession has had ample opportunity to observe its working. Although it is perhaps too soon to know whether the students turned out from these full-time institutions are as good practitioners of medicine and surgery as those educated under more human conditions, it is certain that the productive activity of the professors has not been increased by taking from them the incentive if not the power of growth.

There are hopeful signs that the pendulum has swung about as far in this direction as it will, and that the era of formalism in medical teaching is nearing its limit. A welcome note has been sounded by Dr. Deaver of Philadelphia, who, in his presidential address before the American College of Surgeons last week, expressed himself as opposed to the full-time clinical professorship. The speaker, himself a veteran teacher in a medical school of the front rank, unqualifiedly condemned this new fashion in education, the good results of which he had failed to see. After protesting against the attempted domination of the workers in the world by swivel-chair theorists, he said:

> I am thinking of the recent furor in favor of the full-time teacher in clinical branches. . . . I am not questioning the motives of the originators of this audacious movement, but I am watching for its results, not too brilliant so far, and promising less. I am concerned for the student and would be alarmed for the profession were it not for my great confidence in the sober sense of the great body of a democracy such as this which will eventually work its way toward its own proper method of dealing safely and sanely with conditions. Still I marvel at the new super-intelligence which in rapid pursuit of its ideal sets aside the principle of natural selection, the well-proved motive of human endeavor (high reward), and the cardinal virtue for the attainment of practical results (experience). In my heart I am thankful that such men had no voice in the selection of a generalissimo for the Allied armies.
>
> During the last five years, as you know, the tendency has been toward the full-time clinical teacher. Its central idea was good, but its application, begun before the war, if I mistake not, was influenced by the German idea of efficiency which, as all now know, failed utterly to include the human element in its equation. Without wishing to appear reactionary, but with all interests of the profession in mind, I do not hesitate to say that I doubt the wisdom of the present course. . . . The professor of clinical branches should not only be allowed, he should be obliged, to be in direct professional contact with the public. . . . It is our profound belief that the system of full-time salaried chairs for the clinical branches which has been forced upon a number of our foremost institutions by powerful influence is not only contrary to the spirit of American institutions, and contrary to the proper working of the human mind, but is sure to result in degeneration of that art which is the true flower of science, and in the deterioration of the instruction of the student how to deal effectively with the problems which he must confront in his chosen life work.

Now that Dr. Deaver has had the courage to protest against this full-time fad, we hope others who may have been overawed by the vociferous educational reformers and their powerful backing will come out in support of a return to a sane and rational system of medical teaching. It is argued that the full-time professor has his hospital practice to help him keep abreast of the times and prevent fossilization, but there is a gulf between institutional practice and private practice as wide and as deep as that between organized charity and human sympathy. Imagine such giants as John Warren, Samuel D. Gross, Austin Flint, and Alonzo Clark in the guise of full-time professors!

OXALIC GOUT.

THE relation of oxalemia, as that of other acids in the blood, to gout is one that is still a subject of discussion with no definite solution apparently yet in sight. The subject is reviewed at some length by Loeper in *La Médecine* for July, 1921, ii, 10. Oxalic acid, he states, is the younger brother of uric acid, for while there is no chemical similarity outside of the organism, there is a likeness in their metabolism. Both may be ingested from without; both may be eliminated from the body or precipitated and retained there-

in. One unites with sodium, the other with calcium. Both are irritant and toxic, oxalic acid the more so. Both give rise to gout, both form stones in the urinary passages. Oxalic gout is a subacute articular process with a tendency to produce a hypertrophic, deforming arthritis electing by preference the hands and fingers. While uric acid attacks by preference the cartilages and periarticular structures, oxalic prefers the bones and fibrous tissues. Oxalic gout is termed by Teissier and Roque gouty rheumatism. The *x*-ray shows bone lacunæ and decalcification. In both affections a blood state preexists or coexists—uricemia or oxalemia. Blood serum and blister serum alike contain oxalic crystals. We associate uricemia with hypertension and rushes of blood, oxalemia with hypotension and anemia. In oxalemia there may be neuralgias, myalgias, asthenia, neurasthenia, and melancholia. There is a special urinary pathology to oxalemia—dysuria, hematuria of the occult or cryptic type, renal colic, at times actual inflammation (secondary), and especially calculosis. There are also gastroenteric disturbances, notably flatulent dyspepsia, spasmodic and painful crises, diarrheas and other symptoms connected by the author with crystalline irritation. He believes that one type of gastric ulcer is of this origin. Many obscure conditions which would readily escape diagnosis are attributable to the deposit of oxalic acid crystals in certain tissues. Yet there should be but little trouble in reaching the nature of this condition. It cannot occur in the absence of oxaluria, although one might not be justified in making the diagnosis with simple testing of the urine. The amount is very significant, for this may reach twelve fold the normal. The author and others have devised a blood serum test which is very useful and have found as high as 8 cg. of acid per 1,000 parts of blood. No diagnosis is made in the absence of this blood test. Teissier uses the blister serum test as a substitute.

It is, of course, well known that both uric and oxalic acids may be formed in the body, both without doubt when there is incomplete combustion in the latter. In both cases certain substances like purin bodies favor production. The symptoms are due to elimination—here belong the urinary and gastroenteric—and to deposition, as in the connective tissues, bones, muscles, and nervous tissues, and especially the liver. Treatment involves prohibition of rhubarb and other plants containing oxalic acid; a diet poor in purins and nucleins; no cocoa or chocolate; alkalies; magnesium, which is the chemical antidote; hexamethylenamine, phosphorus to replace the waste of that mineral—usually glycerophosphates. A study of oxalic acid poisoning, such as has occurred from eating rhubarb leaves or when small quantities of the pure acid have accidentally been ingested, shows the picture of gastroenteric, renal, and nervous lesions.

MIXED INFECTION OR CONSECUTIVE INFECTION.

It seems, at the present time, to be the prevailing belief among those who have studied the subject that influenza especially and also measles, or rather the fatalities due to these diseases, are caused by mixed infections. However, this is a theory not yet firmly established, and there is much to be said against it. In an article in the *Edinburgh Medical Journal* for October, 1921, Dr. J. W. Crerar suggests another theory to account for the virulence of certain cases of influenza and measles. He investigated and studied the matter under favorable circumstances, that is in a relatively small urban district where there was a sufficient population to supply a considerable number of cases, and where the conditions of the life of the people were more or less uniform. It was a virulent epidemic of measles studied under these conditions, and after describing it closely from all points of view, but especially in its relation to school attendance, attention was directed to a comparison of this epidemic of measles and the deadly epidemic of influenza in October, November, and December of 1918.

He pointed out that there were certain resemblances, both clinically and statistically, which were at least suggestive. Both were virulent, and in both the so-called complications were integral features of the diseases, at any rate, in the increasing phases of the epidemics. It is a matter of general observation that in a virulent, explosive, apparently self-determining epidemic the patients who are affected as it is tending toward its climax are more seriously ill than those who are affected as it is declining. Crerar's personal experience of the two epidemics under review, confirmed this belief, the complications having been much more frequent and grave in the earlier weeks than in the later weeks of the epidemics.

Attention was drawn with emphasis to the fact observed by him that there was much similarity in the clinical pictures of those gravely ill with pulmonary complications, whether the initial disease was measles or influenza, and the question was asked if this similarity could be dependent on the presence of a similar secondary infection in both cases. Bacteriologists seemed to be agreed that the presence of the pneumococcus and streptococcus was a common finding in cases of acute influenzal pneumonia, and Thursfield had shown, in the Report of Medical Officer of Local Government Board, 1912-13, that streptococcal infection was a preponderant cause of death in measles.

Crerar suggested that it was probable that the fulminating virulence of the primary infection, whether it was measles or influenza, was the occasion of the activity of the other microorganisms, and it was unnecessary to invoke the theory

of a simultaneous mixed infection. He thought it very probable that the devitalizing depression of the original infection presented the opportunity for a sudden loss of resistance to certain microbes which might be normal inhabitants of the throat and nasal passages. Many points of similarity between epidemics of measles and of influenza were traced, but the main object of the writer was to suggest that the theory that the primary infection of either disease started into activity other microorganims was as well supported by facts and as plausible as that of a simultaneous mixed infection.

Statistics of Operations for Mammary Cancer.

Professor Forgue of Montpellier has a personal record of 285 ablations of cancer of the breast, and of this number 115 have "doubled the cape" of the third year of survival. Thirty-three have died of metastases and 18 of intercurrent disease. Forty-two are living without recurrence seven years after operation—about 14 per cent. of the total, and the percentage is improving steadily. He regards a ten-year survival as equivalent to a radical cure, and looks forward to a goal of 10 per cent. of 10-year survivors. This figure agrees fairly with the conclusion of pessimists when they state that 90 per cent. of cancer patients die despite treatment. Thus the author who writes as an optimist really gives the same figures as the pessimist but with a very different interpretation. For him it is an ample justification to use the knife, while for the other it denotes that surgery has not made good. The author realizes the need of standardizing cases for statistical purposes. It is not just to class a cancer in a young woman who has nursed a baby and who comes of a cancerous stock with some of other forms such as, we suppose, a cancer in an elderly thin woman. The late Dr. Murphy regarded the fat woman of 40 as hopelessly doomed. One might, of course, decline to operate in all cases with unfavorable factors, but it is best to group the operated material along certain lines and keep them separate in statistics. This has, of course, been done to some extent, and we know that the survival in cases without axillary adenopathy is high. Professor Forgue read his paper before the recent French Congress of Surgery (reported in *La Presse Médicale* for October 1, 1921, xxix, 79). The discussion brought out the fact that neither Forgue nor Walther, who opened the discussion, regarded radiotherapy as sufficiently developed for final conclusions.

Precocious Diagnosis of Cancer of the Cervix.

Apropos of the campaign of education in the interest of the early diagnosis of cancer some figures of Frankl will serve to point out the obstacles which must be overcome in this direction so far as cervical cancer is concerned. The figures of the German gynecologist are quoted in *La Presse Médicale* for Oct. 8, 1921, xxix, 81. During the period 1901-1912 Frankl saw in his services 1,007 cases of cancer in this location. The percentage in which the disease was in its earliest stage was but 3. In other words, in but three and a fraction out of a hundred cases admitted to the clinic was the diagnosis made either by the microscope only or in the very earliest clinical stage, in which there was a small focus strictly limited to the cervix. Recently the author has compiled a second series of cases which partly overlaps the first. It concerns the number of cancers of the cervix seen between 1909 and 1921. There were 1,011 in this series and the author was pleased to find that 10 per cent. were in the first stage at the first consultation, during the period 1909-1913 inclusive. After the beginning of the war it fell off and during the war years the percentage was between 2 and 3. It is once more picking up, but thus far is but 6.5 for the five months of 1921.

An Alcohol Test Meal.

The use of alcohol as a test breakfast goes back to Carnot in 1904. Ten years later Ehrmann extolled the same resource, while Da Silva Mello took it up in turn, and now, quite recently, San Filippo has made a study of the same. Dr. Sabrazès, editor of the *Gazette hebdomadaire des sciences médicales de Bordeaux* (August 3, 1921, xlii, 32), gives the technique of the method as follows: The stomach is first washed out and 300 c.c. of an aqueous solution of alcohol, 5 per cent., with about twenty grains of sodium salicylate, is allowed to remain half an hour. The clearness of this solution makes it very easy to recognize ingredients like blood, bile pigment, mucus, and formed elements. Free and combined HCl and total acidity are tested for in the usual way. Additional reasons for preferring alcohol to the Ewald-Boas meal are not stated unless they comprise the saving of time, for when the latter is used the stomach is not siphoned for an hour later. The irritant action of the alcohol is less efficacious than the normal stimulus of the food in the production of acid secretions, and according to Sabrazès the values are much lower. This applies also to the reflux through the pylorus.

News of the Week.

International Endorsement of the Speedwell System.—At the International Congress for Child Welfare held at Brussels last summer, the congress favored the organization throughout Europe of the unit method of boarding-out as operated according to the Speedwell system in use in the United States. The Speedwell Society was organized in New York twenty years ago when this method was inaugurated and it has employed it ever since. The operation of the Speedwell system was first described in the Medical Record in two articles by Dr. Henry D. Chapin. The first, was entitled "The Proper Management of Foundlings and Neglected Infants," published February 18, 1911; the second, "Problems of Boarding Out, with an Attempted Solution," April 24, 1920.

American Death Rate in 1920.—The Government's annual report on mortality statistics for 1920, soon to be issued, shows a total of 1,142,578 deaths within the death registration area, representing a rate of 13.1 per thousand population, as compared with 12.9 in 1919, which was the lowest

recorded in any year since establishment of the registration area in 1900. There was an increase in the death rate from pneumonia and a marked decrease in tuberculosis fatalities.

Question of Contract Practice Rends Medical Societies.—The Spokane (Wash.) Medical Society, at a meeting on October 14, refused to rescind its action demanding the surrender by its members of contracts with corporations for professional services. This action was taken after the Board of Trustees of the Washington State Medical Society issued an edict to the county society demanding that the anti-contract law be rescinded on penalty of permanent suspension from membership in the State Society in the event of failure to comply within thirty days. It is held by the county society that this order is not effective unless ratified by the House of Delegates of the State Society, which does not meet until next September. Meanwhile the county society has ordered to appear before it all doctors who hold contracts to show cause why they should not be expelled from membership. The society is said to have thirty-five members holding forbidden contracts. These doctors, it is said, have taken the stand that they will leave the society rather than give up their contracts.

Inefficiency Due to Imperfect Sight.—The Eye Sight Conservation Council of America has recently made public the results o fa careful examination of 10,000 industrial and commercial workers active in their work and supposedly in good condition, of whom 53 per cent. showed defective vision uncorrected. It was found that many employees are accused of inefficiency and carelessness when it is entirely a matter of imperfect vision. The report urges that just as it is necessary for school children to be examined, so every individual between the ages of twenty-one and thirty-nine years should have the ocular state ascertained, as was done in the case of the army draftees.

Smallpox in Bethlehem, Pa.—A senior student at the Moravian College and Theological Seminary was recently found to be suffering from smallpox. The college has been quarantined, classes have been suspended, and the entire student body and faculty vaccinated.

Smallpox in New York.—Recently two negroes suffering from smallpox were removed from the same house in Harlem within the period of one week. Neither of the men had ever been vaccinated.

Births and Marriages Increase in Paris.—The vital statistics records of Paris show many more births and marriages for the first six months of 1921 than before the war and also a reduction in the infant mortality rates in the crowded districts of the city. There were 31,885 births in Paris during the first six months of 1921, as compared with 24,300 in the same period of 1913 and 27,906 in the first half of 1920. The number of marriages in all of 1913 was only 31,916, while last year there were 53,829, and there have been 26,282 weddings in the first half of 1921.

Tuberculosis Clinics in Ohio.—A conference was held in Columbus on October 16 to plan for tuberculosis clinics to be held in forty counties of the State during the coming winter. These clinics will be under the direction of the State Health Department, each clinic being directed by the local health commissioner. Tuberculosis specialists will conduct the examinations and report their findings only to the physicians of the patients and to health officials. Each clinic will be held for two days during which time it is expected that about sixty examinations will be made.

Cornell University Medical College to Start Pay Clinic.—A pay clinic under the direction of the Cornell medical faculty will be opened at Cornell University Medical College on November 1. According to its announcement the clinic is designed to meet the needs of persons of moderate means unable to pay high class specialists' fees, but who, because they are not paupers, are unable to enjoy the advantage of the charity clinics. The price for each visit will be $1; medicine, laboratory tests, *x*-ray photographs and other supplies will be given at cost. The diagnosis of a case requiring special examinations and study, with group consultation of specialists and a written diagnosis will cost $10. A thorough physical examination to discover possible defects and diseases and to obtain advice regarding personal hygiene will cost $2.50. It is estimated that there are in New York City 2,000,000 persons who fall between those who are so poor as to be unable to pay for medical services and those who are well-to-do and able to pay full rates for whatever they need in time of sickness. The doctors who provide the medical service are to receive a salary.

Thyroid Feeding for Subnormal Children.—Under the direction of the Chicago Health Department an experiment is to be carried out to determine the effect of feeding thyroid extract to children in the subnormal classes. The sheep glands used for the feeding are to be prepared in the school kitchens and the school doctors will note the accompanying results.

Graduate School of Medicine in Atlanta.—A newly organized Graduate School of Physicians and Surgeons to be established at Atlanta, Ga., plans to do work similar in scope to that of the graduate medical schools in the larger cities of the country. The new school will be the only institution of its kind in the southeastern States. It is expected that the school will be opened some time in March, when the new building to be erected at a cost of $150,000, will be ready.

Physicians of Waukegan Scale Prices.—The secretary of the Waukegan (Ill.) Medical Society states that physicians in that locality reduced their charges to pre-war levels as early as last June. The present scale of prices is as follows: Day calls, $3; night calls, $6; office calls, $2.

Red Cross Roll Call.—The New York Chapter of the American Red Cross announces that the 1922 Red Cross Roll Call will be conducted from November 11 to 24, when an effort will be made to enroll at least 500,000 dollar members in Manhattan alone.

Physicians Requested to Aid Research Work in Whooping Cough.—In its work of investigating the value of pertussis vaccine the Bureau of Laboratories of the New York Department of Health is badly handicapped because of the diffi-

culties of obtaining material from early cases of whooping cough. Most of the notifications received by the department are of cases well along in the disease and are, therefore, unsatisfactory for cultural examinations. For this reason physicians are asked to notify the Bureau of Laboratories of early cases of whooping cough, in families who would be willing to have a representative of the department visit them and obtain material for cultural examination. The department also wishes to obtain material from children who have been exposed to infection and who show signs suggesting the onset of the disease.

Tuberculosis Decreases in New York City.—The number of new cases of tuberculosis reported in New York City in 1920 was 14,035, as contrasted with 14,570 new cases reported in 1919, a decrease of 435 cases, or 4 per cent. as compared with the previous year's registration. This decrease was limited to the boroughs of Manhattan, Bronx, and Brooklyn. In Queens there were 340 more new cases than during the preceding year. These are mostly so-called "home cases" and without medical supervision. During the year 1920 there was a grand total of 23,240 patients who attended the clinics of the Department of Health. Of this number 15,065 were discharged as non-tuberculous. In all there were 75,803 visits made by patients to the tuberculosis clinics during the year.

Hospital Notes.—Roosevelt Hospital, New York, founded on November 2, 1871, by the will of James H. Roosevelt, celebrated its fiftieth anniversary during the week beginning November 1. The hospital since its opening has taken into its wards and rooms over 250,000 patients, and has treated in its dispensary 1,080,000 cases. The $1,000,000 left by its founder has grown by appreciation and gifts until the hospital to-day is worth more than $1,500,000 and has investments worth more than $2,000,000.

A campaign to raise $125,000 for the American Hospital for Diseases of the Stomach, Philadelphia, was conducted during the week of October 26. The hospital now has forty beds which are occupied constantly and needs the $125,000 for an additional building.

Plans have been submitted for a new $100,000 building for the Wyoming Valley Homeopathic Hospital at Wilkes-Barre, Pa. Construction work will be begun within a few weeks.

The Board of Commissioners of the Louisiana Hospital for Insane at Pineville, La., have awarded contracts for the erection of four large buildings for the hospital. The contracts call for three dormitories to cost $231,000 and a dining hall to cost $201,300.

The Southern Homeopathic Medical Society is preparing plans for a $250,000 Hahnemann Hospital for Southern California.

A Methodist Hospital to cost $300,000 to $375,000 is being planned and financed by the Methodist Episcopal Hospital Board of the State of Oregon.

Gift for Research Work.—A gift of $25,000 from the estate of Mary Anne Palmer Draper for the establishment of a fund for laboratory and surgical research at New York University was recently announced by Vincent Roberts, chairman of the university's endowment fund committee.

Senior Surgeon R. L. Cook of the United States Public Health Service has succeeded Major M. H. Axline as officer in charge of the hospital at Camp Logan, Texas.

Dr. Charles W. Pilgrim has tendered his resignation as chairman of the New York State Hospital Commission, to become effective on December 12.

Dr. Harvey Cushing of Boston was elected president of the American College of Surgeons at its recent meeting in Philadelphia.

To Erect Gorgas Memorial.—At a meeting of the Board of Directors in Philadelphia on October 26, officers of the Gorgas Memorial Institute Committee, which plans to erect in Panama a suitable memorial to the late Surgeon General of the United States Army, were elected. They are: *President*, Rear Admiral William C. Braisted, U.S.N.; *Vice-President*, Dr. Franklin H. Martin, Chicago; *Executive Secretary*, A. F. Robbins, Chicago; *Treasurer*, Edward J. Stellwagen, Washington, D. C.; *Assistant Treasurer*, Edson B. Olds, Washington, D. C. Panama was selected as the site for the proposed memorial. The funds will be solicited from scientific and philanthropic organizations and from individuals. Present plans call for the momorial to take the form of an institution devoted to research work.

Harvey Society Lecture.—Dr. C. C. Little, Research Associate of the Station for Experimental Evolution, Carnegie Institution of Washington, will deliver the second Harvey Society Lecture at the New York Academy of Medicine, Saturday evening, Nov. 26, 1921. His subject will be "The Relation of Genetics to Cancer Research."

Lectures on Experimental Medicine and Therapeutics.—Dr. Alexander Marmorek announces that he will deliver a series of sixteen lectures, in English, on experimental medicine and therapeutics at the Institut Océanographique, 195 Rue St. Jacques, Paris. These lectures will begin on November 21. Further information may be obtained by writing to Dr. Marmorek at the above address.

The American Academy of Applied Dental Science will hold its third annual meeting at the Stacey-Trent Hotel, Trenton, N. J., January 9, 10, and 11, 1922. Papers, clinics and class demonstrations will be the special features of the meeting. A cordial invitation is extended to all members of the medical and dental professions. Further information may be obtained by addressing the Assistant Editor, American Academy of Applied Dental Science, Yonkers, N. Y.

Scholarships for Post-Graduate Study.—The New York Post-Graduate Medical School and Hospital announces that there are now available several scholarships under the terms of the Oliver-Rea Endowment. The purpose of the Endowment is to further post-graduate medical education by awarding scholarships to practising physicians of the United States. The scholarships vary in amount but are sufficient to defray in full or in part the tuition fees of the Post-Graduate Medical School for the courses offered. According to the wish of the donor, physicians in the State of Pennsylvania will receive preference in the award of these scholarships. Applica-

tion may be sent to the Dean of the New York Post-Graduate Medical School and Hospital, Twentieth Street and Second Avenue, New York City.

Chairman Chosen for Semi-Centennial of American Public Health Association.—In preparation for the Health Fortnight to be held in New York from November 8 to 19, the Fiftieth Annual Meeting of the American Public Health Association, Dr. Lee K. Frankel, former President of the American Public Health Association, has been chosen General Chairman of the Centennial Committee. One of the features of the Health Fortnight will be the Health Institute, from November 8-11, which will offer visitors an opportunity to witness in actual operation every phase of health work conducted in this city. Sunday, November 13, will be Health Sunday, and the cooperation of the leading churches is expected in bringing the message of health to the people. The week beginning November 14 will be devoted to the Fiftieth Annual Meeting of the American Public Health Association, to be held at the Hotel Astor, and to the Public Health Exhibition in the Grand Central Palace.

Medical Society Elections.—The Fifth District Branch of the Medical Society of the State of New York, at its fifteenth annual meeting held in Watertown, October 6, 1921, elected the following officers: *President*, Dr. Walter Kidder, Oneida; *First Vice-President*, Dr. Nelson Brooks, Oneida; *Second Vice-President*, Dr. C. D. Post, Syracuse; *Secretary*, Dr. C. B. Forsythe, Alexandria Bay; *Treasurer*, Dr. Nelson Brooks, Oneida.

The Northwestern Ohio District Medical Society, at its annual meeting held in Toledo, October 7, 1921, elected the following officers for the ensuing year: *President*, Dr. Charles H. Clark, Lima; *First Vice-President*, Dr. W. C. Pay, Bellefontaine; *Second Vice-President*, Dr. Thomas Hubbard, Toledo; *Secretary*, Dr. Norris Gillette, Toledo; *Assistant Secretary and Treasurer*, Dr. R. J. Morgan, Van Wert.

The University Club Medical Society, Washington, D. C., was organized on October 5, 1921, with the following officers for the ensuing year: *President*, Dr. Noble P. Barnes; *Vice-President*, Dr. George T. Vaughan; *Secretary-Treasurer*, Dr. Everett M. Ellison; *Editor*, Dr. John Foote; *Sergeant-at-Arms*, Dr. Edward G. Seibert.

The Columbia County (N. Y.) Medical Society, at its annual meeting held in Hudson, Oct. 4, 1921, elected the following officers for the ensuing year: *President*, Dr. Henry C. Galster; *Vice-President*, Dr. John L. Edwards; *Secretary-Treasurer*, Dr. Charles R. Skinner.

The South Texas District Medical Society, at its semi-annual meeting held in Galveston, Oct. 14, 1921, elected the following officers for the ensuing F. R. Winn, Alvin; *Vice-President*, Dr. W. S. Foote, Bay City; *Secretary*, Dr. J. E. Clarke, Houston.

The Wyoming County (N. Y.) Medical Society, at its annual meeting held in Warsaw, Oct. 12, 1921, elected the following officers for the ensuing year: *President*, Dr. George G. Davis; *Vice-President*, Dr. Lemar M. Andrews; *Secretary-Treasurer*, Dr. George E. Skiff.

The Southern California Homeopathic Medical Society, at its annual meeting held in Los Angeles, Oct. 12, 1921, elected the following officers for the ensuing year: *President*, Dr. Bradford Fox, Pasadena; *First Vice-President*, Dr. Edward P. Clark, Los Angeles; *Second Vice-President*, Dr. Florella Estes, Los Angeles, *Secretary-Treasurer*, Dr. Charles Salisbury, Los Angeles.

The Three Counties Medical Association (Cal.), at its annual meeting held at Fall River Mills, Oct. 9, 1921, elected the following officers for the ensuing year: *President*, Dr. M. D. Pratt; *Secretary*, Dr. M. Tinsman; *Treasurer*, Dr. J. J. Quinne.

Obituary Notes.—Dr. Dwight H. Murray of Syracuse, N. Y., died suddenly of heart disease on Oct. 26, at the age of sixty years. He was graduated from the Syracuse School of Medicine in 1884 and afterward studied abroad. He was a Fellow of the American College of Surgeons and the American Medical Association; a member of the American Proctological Society, the American Pathological Association, the New York Academy of Medicine, and the Syracuse Academy of Medicine. Dr. Murray was speaker of the House of Delegates of the American Medical Association and vice-speaker of the House of Delegates of the Medical Society of the State of New York. He was a former president of the Onondaga County Medical Society. Dr. Murray was on the Board of Managers of the Onondaga Sanatorium and was proctologist to the Good Shepherd and Memorial Hospitals.

Dr. Jehiel H. Patrick of New York City, a graduate of New York University Medical College in 1893, died of heart disease on Oct. 27, at the age of fifty-four years.

Dr. Jonathan Titus Deyo of Brooklyn, N. Y., died suddenly of heart disease on Oct. 26, at the age of seventy-five years. He was graduated from the New York Homeopathic Medical College in 1870.

Dr. Henry J. Blankmyer, Jr., of Gabriels, N. Y., a graduate of Jefferson Medical College in 1903, died suddenly in Philadelphia on Oct. 22, at the age of forty-two years. He was head of the tuberculosis sanatorium at Gabriels, N. Y.

Dr. John Wilson Gibbs of New York, a graduate of the New York Eclectic Medical College in 1878, died on Oct. 28, at the age of seventy-five years.

Dr. Charles L. McCann of Brooklyn, N. Y., died of heart disease on Oct. 19, at the age of seventy-four years. He was graduated from New York University Medical College in 1871.

Dr. W. H. Burt of Atlanta, Ga., a graduate of Emory University School of Medicine in 1880, died Oct. 15, at the age of sixty-two years.

Dr. J. P. Graham of Portland, Ore., a graduate of the University of Oregon Medical School in 1909, died from the results of injuries sustained in an automobile accident on Oct. 12, at the age of thirty-eight years. He served as major in the Medical Corps of the United States Army during the late war.

Ira Darius Spencer of Croghan, N. Y., a graduate of the Eclectic Medical College of the City of New York in 1889, died following an operation on Oct. 11 in a Watertown hsopital, at the age of fifty-four years. He was health officer of Croghan and a member of the state legislature in 1902.

Dr. Vera Barky, formerly of Germantown, a graduate of the Women's Medical College of Pennsylvania in 1878, died suddenly in Cape May, N. J., on Oct. 21, at the age of seventy-five years.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Oct. 14, 1921.

Opening Address at the Middlesex Hospital School.—Mr. G. Gordon Taylor gave the address at the opening of the winter session of the Middlesex Hospital School on Oct. 4 last. His subject was "The Dramatic Side of Surgery." Mr. Taylor said in part that dramatic and spectacular surgery might be, and often was, the result of brilliant and exquisite achievement. It might indicate the conquest of difficulties unexpected or those against which no definite provision had been made. Every surgeon probably derived some pleasure from the successful removal of a large tumor, and the enumeration of the weight and linear dimensions of their trophies denoted a spirit of rivalry and competition on the part of the operators for a place on the list, arranged not in order of the dexterity of the surgeon, but according to pounds and feet of the particular organ or organs removed. He shared in full the foibles of his surgical confrères. He was still proud of the successful extirpation of a 17½-lb. renal tumor two months ago and of a lady's gall bladder which had attained the size of a large cucumber, and which in a mistaken diagnosis of intestinal stasis had been treated by the application of a heavy cannon ball rolled round her abdomen. His late chief, Sir John Bland Sutton, was a dramatic operator, partly because of his speed and also by reason of the few implements which he required, they were contained in a tiny case which could be carried on one finger. Mr. Taylor then spoke of the surgical experiences of the war, and drew attention to the value of aeroplanes in conveying the wounded long distances if necessary. He, however, pointed out that this was no new departure, as wounded men were carried considerable distances in the Somali campaign against the Mullah, and one man, at least, was conveyed 225 miles for an amputation of a lower limb. Mr. Taylor discussed transfusion of blood at some length, and mentioned Holmes A. Court's dramatic case of ligature of the common carotid artery for a penetrating wound from which a man was bleeding to death, and an immediate blood transfusion which saved his life. That was the only case he knew where an immediate operation of this nature resulted happily. Some patients might be said to have many lives. An Australian lieutenant was gassed in the beginning of June, 1918; on July 4, on the way to the trenches, he was wounded in the abdomen by a fragment of shell. By a lucky chance he was near an advance dressing station, whence he was speedily transferred to Mr. Taylor's casualty hospital and had to be prematurely sent down to a base. Here he was sorely tempted to eat of forbidden food and fruit at the hands of the V. A. D.'s and nurses, but he courageously braved the unpopularity which he incurred by turning a deaf ear to their blandishments. On his way across the English Channel he was torpedoed in the hospital ship *Warilda* and dragged out of the water by a rope round his waist. He spent two hours in a boat in soaking pajamas and subsequently six hours on the deck of a destroyer. Yet he made a complete recovery and now found Paris a pleasant spot in which to sojourn as a fruit dealer. Sir John Bland Sutton, consulting surgeon to the hospital, presented the prizes to the students and the Fardon memorial medals to the nurses. In reply to a vote of thanks, he gave an amusing account of his earliest experience of prizes. His first prize, obtained at the Middlesex Hospital School, was one for botany, and the then dean, a very good churchman, when he said he wanted Darwin's "Origin of Species" for his prize, said that he did not think that was a proper book for a medical student to have, but that he might have it. When he found he was entitled to a second book he asked for Dante's "Inferno" to please the dean. He once won the Murray gold medal, and he shut it up in a box and occasionally had a look at it, but it seemed to him at times to be a terrible waste of money. After he had heard at church about the hiding of the talents, he went to a goldsmith, who said to him: "I cannot let you have anything on the medal unless you let me cut it in half, for we know that the men who make these medals have a knack of putting a piece of lead in the middle." Sir John replied that the medal was given him by the Middlesex Hospital, which would never lend itself to such reprehensible practice. But he would cut it in half, and how that man must have chuckled when he saw that in the middle there was a lump of lead. He thought the Royal Society was right in asking people not to leave their money to provide gold medals, but for research and for scholarships.

Scientific Research at the British Universities.—It is lamentable but unfortunately a fact that scientific research, and perhaps medical research, in particular, has not made any great headway in Great Britain. Of course, the reason is obvious—namely, that the general public, being ignorant of the value of such work, grudge the expenditure of money upon it. No immediate material benefits are seen and therefore the conclusion is jumped at that research of this kind is useless and a waste of money. Neither do the rich here, with but few exceptions, appreciate the value of scientific research, and are chary of rendering financial aid. In this respect they differ widely from the moneyed men of America, who have for long recognized that scientific research properly conducted, although it may not show quick results, in the long run pays fourfold. Any steps that tend to the welfare of the people at large are of the greatest benefit to the nation. And industrial and medical research certainly do tend in this direction. However, there is no need to labor this point, to the far-seeing and intelligent it is obviously apparent. While research work of whatever description in this country has seldom been financed, and it is really remarkable the discoveries that have been made in Great Britain under these conditions, the situation has undergone, to some extent, an encouraging change, and an increasing amount of research work is now financed. The Department of Scientific and Industrial Research has a relatively large

fund to be administered for research, which, as the scientific correspondent of the *Times* points out, is under conditions which it has not yet completely succeeded in strangling by red tape. This correspondent also aptly refers to these research departments as the Marthas of science, among which, of course, are included the Medical Research Council, which, by the way, takes wider views than some of the other departments. Physical energy is what the world hungers for, and consequently research efforts are especially concerned with physics, and it may be said that medical schools are establishing chairs of physics. The fractional distillations of Crookes led the way to colloidal therapy and many other discoveries which seemed remote from practical utility have proved themselves of use from medical and various standpoints. For example, Ramsay's reweighing of the inert gases, the Curies' work on the heavy earths, J. J. Thomson's investigations on electrons, Soddy's isotopes, Astron's spectroscopy, Rutherford's investigations of radiographic emanations, and many more researches of a somewhat like nature. As an outcome of these researches changes may eventuate which will revolutionize the fabric of civilization and exert an equally profound influence on medicine. Chemotherapy, which is yet in its infancy, but which is growing apace, seems as if it might become the main treatment of the future. Its possibilities are immeasurable. The consummation of successful treatment of disease can only come to pass by means of continuous and persistent research. For this purpose money is required. Other things being equal, the investigator who has at hand the most recent and best laboratory equipment will forge ahead the most surely and rapidly, and the nation of which he is a member, largely because it is the most healthy, will be the most prosperous. Therefore, scientific research, of which medical research is the most essential part, should not be starved or stinted. Education is needed in this country to drive home these palpable truths.

Reduction of Panel Doctors' Fees.—The Government proposes, Sir Alfred Mond, Minister of Health, told a deputation from the British Medical Association Insurance Acts' Committee, which waited on him on Oct. 11 last, to reduce the fee of panel doctors for each patient after Dec. 31 from eleven shillings to nine shillings sixpence on the ground of the urgent need for national economy. Dr. Brackenbury, chairman of the Insurance Acts' Committee, said that the offer of the Minister of Health would be placed before the Panel Conference, to be held on Oct. 20, for their consideration. The medical *Press and Circular*, Oct. 5 last, is very outspoken on the matter. In an editorial it is said that the Insurance Act furnishes an unsavory chapter in the history of the profession of our time. The bill was introduced for political reasons, and a portion of the profession was cajoled into supporting it and it became law. It seems that the threatened action to reduce the capitation fee will meet with strong opposition from the medical profession as a whole, although Sir Alfred Mond pleaded that the doctors should submit to it for the good of the nation. In any event it has been demonstrated that politics and matters of health should be kept apart. It has also shown how impotent doctors are politically. They are mere pawns in the game, and unless they organize and present a united front they will continue to be so. If the Minister of Health refuses to concede their demands, in all probability the Insurance Act will snuff out. Its extinction will cause few regrets, its working is hampered and hindered by red tape, and it appears to be unpopular with the bulk of the profession and more so with the patients.

Mr. James Berry, F.R.C.S., Installed as President of the Medical Society of London.—At the one hundred and forty-ninth session of the Medical Society of London Mr. James Berry, who, by the way, is a Canadian by birth, was inducted into the presidency of this old and honorable society. As is usual on such occasions a presidential address was given. Mr. Berry in his address departed from time-honored custom and, instead of delivering a learned disquisition on operative procedures in exophthalmic goiter or on some other branch of which he is an acknowledged master, related some of his medical experiences in southeastern Europe, illustrated by lantern slides. An address of this nature was really an agreeable change. It was by no means wholly concerned with medical experiences, but dealt lightly with anthropology, archeology, geology, customs and habits of the people, scenery, and so on. Mr. Berry showed himself to be a fascinating lecturer, he was humorous and witty and displayed remarkable descriptive powers and, moreover, he was commendably brief.

London Medical Exhibition.—The eleventh London Medical Exhibition was held in the Central Hall, Westminster, from Oct. 3 to 7 last. Among exhibits of a directly surgical nature were the catgut and Sontar needle shown by the London Hospital. Several American firms were represented at the exhibition. It was an extremely good exhibition, well arranged and well attended.

England's First Radium Hospital.—The new hospital of the Manchester and District Radium Institute was opened on Oct. 7 last by Lord Derby. It will be the first hospital in this country to be used exclusively for radium treatment.

Obituary.—The death has taken place at Edinburgh of Major-General Peter Stephenson Turnbull, M.D., aged 85, an honorary surgeon to the King. Major-General Turnbull joined the Indian Medical Service in 1860 and served in Abyssinia in 1867 and 1868 under Lord Napier of Magdala. Major-General Turnbull held the appointment of Principal Medical Officer for the Sind district from 1888 to 1893, in which year he became Surgeon-General to the Government of Bombay, retiring three years later.

WARNING AGAINST SWINDLERS.

To the Editor of the Medical Record:

Sir:—We have been advised that a person who has not been in our employ since 1917 has recently obtained loans from physicians in New York City.

We assume that the man secures the loans on the strength of his former connection with us or he tells

those whom he approaches that he is still in our employ. We hope to protect your readers from such misrepresentations.

Since access to us is so easy, our representatives can readily secure funds should they require them.

1. Etiology and Pathology of Loss of Vision from the Accessory Sinuses.—Leon E. White, summarizing a lengthy article on this subject, says that earlier writers considered the anatomical relations of the optic nerve to the accessory sinuses the chief factor. Later ones claimed the trouble was transmitted by the soft tissue. No one etiological factor is responsible for all cases. Purulent infection accounts for a few, while hyperplasia seems of minor importance. The analysis of a considerable number of case records indicates that the size and position of the middle and superior turbinates probably explain the etiology in a large number. Poor ventilation and faulty drainage are all important predisposing causes. He discusses the pathology under four headings, namely, direct extension, toxemia, bacteriemia, and hyperplasia. (1) By direct extension acute infections in the adjacent sinuses spread by continuity of structure to the sheath of the nerve, or even to the optic nerve itself, while in the more remote sinuses the infection becomes walled off. Nature has so walled off the chronic infections that it is futile to longer believe purulent sinus disease the one and only etiological factor. Cases with sudden loss of vision with such noses might better arouse suspicion that the cause should be sought elsewhere than longer be considered the *sine qua non* of accessory sinus blindness. A comparison may be drawn between optic neuritis and Bell's palsy. (2) Toxin originating in the accessory sinuses or elsewhere may involve the optic nerve. (3) Microorganisms may be carried into the blood stream or lymph channels from the foci of infection in the sinuses to the regions adjacent to the optic nerve. Hematogenous focal infection of the nervous apparatus has been demonstrated, so why not a similar involvement of the optic nerve? (4) Hyperplasia, a predisposing factor, is probably of considerable importance, but not *per se*. Hyperplasia, plus infection and direct extension to the optic nerve, is responsible for many cases. Cultures when taken all gave the same growth, *Staphylococcus albus*. A few streptococci were found, but no viridans were isolated. Several of the sections showed considerable increase in leucocytes and fibroblastic tissue along the margins of the bone. Others showed chronic inflammation of the deeper elements of the mucosa and of the bone, while a few showed fibrous hyperplasia.

3. Overweight in Children.—William R. P. Emerson believes that overweight in children has not received the attention from either parents or physicians that its serious menace to health warrants. When the excess of weight passes twenty per cent. beyond the average the condition is called obese. A comparison of defects in 24 underweight and 24 overweight children, shows that the underweight child averages nearly six defects, while the overweight child averages less than two. Cases are common in which it is impossible to find a single physical defect in the overweight child. Nevertheless the symptoms of overweight are shown in the tax put upon the heart and other vital organs by the extra burden of weight carried. From this condition come lessened powers of endurance and diminished activity. Owing to the extra burden placed upon the lungs and circulation the overweight child is less likely to recover from pneumonia or other acute infection. Joslin states that obesity is a predisposition to diabetes. The chief cause of obesity is the habitual intake of more food than is called up usually carbohydrates and fats. It is remarkable how general is the idea, even among physicians, that the usual cause of obesity is some abnormality of the endocrine glands. The use of thyroid extract in the treatment of obesity is a short cut attended with danger to the growing tissues and is seldom, if ever, necessary. The remedy for overweight is measured feeding. If there is no loss of weight with a reduction of one-third the amount of food usually taken, a further reduction of 100 calories per day should be made, until it is found what amount of food will bring about the desired weight loss. If the loss in weight does not exceed from one-half to two pounds, depending upon the weight of the child, the child will feel better while the reduction is going on. Moderate exercise which is not overfatiguing will also assist the process of reduction.

5. Roentgen Ray Therapy in Chronic Diseases of the Bones, Joints and Tendons.—Herman B. Philips and Harry Finkelstein relate their experience with roentgen therapy during the past two years at Hospital for Joint Diseases, New York, in the treatment of such conditions as tuberculous arthritis, chronic pyogenic osteomyelitis, chronic arthritis, chronic tenosynovitis, etc. They assert that roentgenotherapy is available as probably the greatest but least used therapeutic agent in the orthopedist's armamentarium. Night cries, muscle spasm, uncontrollable pain, temperature, and malaise frequently disappear after a few radiations. Sequestration is favored by *x*-ray radiation. The chronicity of osteomyelitis is markedly shortened. Drainage by radiation from deep seated abscesses is favored. Chronic sinuses dry up and are obliterated. The degenerative processes in ganglia are checked by radiation with resulting disappearance of the ganglia. Chronic tenosynovitis is similarly affected. Orthopedic and surgical measures are aided and not replaced by *x*-ray therapy. Braces, casts and the like should not be discontinued during the treatments, until definite cures have been established. A strong plea is registered for a greater adaptation in a clinical way of roentgen therapy. Technique is now established on an absolutely safe basis, and careful observation of the patient with intelligent administration of stimulating doses can do no harm, but on the contrary can save considerable time to the patient, as well as at times life and limb.

8. The Rectovaginal Septum in Proctology.—Descum C. McKenney reminds proctologists and gynecologists that they have a common interest in the treatment of diseases involving the anorectovaginal septum. Repair of the septum on the vaginal side has been made by gynecologists with little or no thought of the alleviation or cure of anorectal diseases, likewise rectal conditions have been treated by the proctologist without

proper regard for the great necessity of coincident repair of the septum. Internal hemorrhoids that do not prolapse are usually cured by repair of the septum alone. When rectocele has associated with it disease of the cervix and anterior vaginal wall, requiring surgical intervention, all should be given attention at one operation. In clean cases there should be no hesitation in repairing the septum at the same time that one does the necessary anal or rectal operation. There are many methods by which this may be done, if one bears in mind certain general principles upon which are based the successful operations. These are: The separation and elevation of the posterior vaginal mucous membrane from the rectal wall as far upward as the cul-de-sac, if necessary; the infolding of the rectal wall and the maintenance of it in this position by bringing together above the told the rectovaginal layer of endopelvic fascia; the formation of a new perineal body by bringing together from either side the edges of the levator ani muscle and other structures intimately associated with it; the obliteration of all dead space; the trimming away of redundant vaginal mucous membrane.

11. The Simulation of Epidemic Encephalitis by Drug Poisoning.—George Wilson reports the case of a woman, about forty-two years of age, who following an operation for appendicitis made an uneventful surgical recovery. Because of persistent insomnia she was given five grains of luminal every night for six nights without any results until after the fifth dose had been taken, after which she complained of headache and double vision, went to sleep, and remained in a stupor for six days. During this time she presented the characteristic appearance of a patient suffering from epidemic encephalitis. A gradual recovery ensued. A second patient was admitted to the Philadelphia General Hospital with symptoms simulating those of epidemic encephalitis. He remained in lethargy for three days, after which he became mentally brighter and stated that three days before admission he had a cold and bought half a pint of whiskey from a bootlegger. He said the whiskey had a peculiar taste and smell. Wilson said he reports the case of luminal poisoning because since Dercum's paper on the value of luminal in epilepsy, that drug has been widely used in the treatment of epilepsy, but little as a straight hypnotic. In the case herein reported it was used as a hypnotic and the symptoms developed after the administration of twenty-five grains. It is important that it should be generally recognized that intoxications can simulate epidemic encephalitis.

14. Hepatic Fever Due to Gumma of the Liver.—G. A. Friedman describes the case of a patient admitted to the hospital with a diagnosis of right lower lobar pneumonia, with persistent cough, pain in the right side of the chest, great weakness and fever. The *x*-ray and clinical examination revealed an enlarged right lobe of the liver. These findings together with that of a positive Wassermann reaction suggested the diagnosis of gumma of the liver. Under appropriate treatment there was a quick return to normal which confirmed this diagnosis.

3. Lymphocytosis as a Diagnostic Sign of Periapical Infection in Adults.—Judson Daland calls attention to small cell lymphocytosis with a corresponding decrease in the polymorphonuclear cells as an important diagnostic sign of periapical dental infection, the value of which is increased when leucopenia coexists. In a study of one hundred cases of chronic disease when no focal infection existed lymphocytosis was found only twice. Lymphocytosis indicates that toxins or streptococci or both are entering the blood. Lymphocytosis disappears from five to eight weeks after the removal of all foci of infection. If it persists after the removal of a periapical infection it usually indicates the presence of an undiscovered focus of infection. The organism that produces lymphocytosis is usually *Streptococcus hemolyticus* or *Streptococcus viridans*. An area of chronic periapical dental infection not communicating with the mouth cavity is usually composed of streptococci and inflamed tissue and seldom contains pus, contrary to the prevailing opinion that it is always purulent.

9. Surgery Versus Roetgen Ray in the Treatment of Hyperthyroidism.—George W. Crile reviews the literature in reference to the value of the roentgen ray in hyperthyroidism and states that at the Lakeside Hospital, Dr. Christie has made a series of comparative studies of the effects of reontgen rays, of ligation, and of thyroidectomy on the basal metabolism. He has found that bilateral partial thyroidectomy reduces the metabolism more markedly and more promptly than either roentgen rays or ligation; and that roentgen rays reduce the metabolism more than ligation. Since Dr. Christie's findings appear to show that thyroidectomy exerts the greater immediate curative effect, it becomes necessary to determine whether or not there are other considerations which should prohibit the employment of thyroidectomy in preference to roentgen rays. To determine this a comparison of thyroidectomy and roentgen rays were made as to (*a*) the resultant discomfort; (*b*) the resultant period of disability; (*c*) the immediate mortality; and (*d*) the end results. As the operation is being performed at the Lakeside Hospital (in the patient's room without removing the patient from bed), no discomfort follows the preliminary ligation; and there is relatively little discomfort after the thyroidectomy. It therefore follows that this plan of surgical management produces no greater subjective disturbance of the patient than results from transportation to and from the roentgen ray treatment room. As to the period of disability, in a recent series of 500 thyroidectomies, the total average stay in the hospital was twenty-five and one-fourth days—broken by the period at home between ligation and thyroidectomy. The mortality in this series of 500 thyroidectomies was 1 per cent.; among the last 500 ligations there were 2 deaths, a mortality of 0.4 per cent. The Lakeside Hospital records show 476 consecutive thyroid operations without a death, showing that operative risk may be largely disregarded under the type of surgical management advocated by the writer. It is too early to report on the end results in this series as at least three years should elapse before the end results may be considered as stabilized. In view of the evidence at hand it must be considered that surgical reduction of hyperthyroidism is altogether the most curative method.

10. Anesthesia in Nose and Throat Work: Further Report of the Committee on the Advantages and Disadvantages of the Various Local Anesthetics in Nose and Throat Work.—Emil Mayer, Ross Hall Skillern, Robert Sonnenschein, and William B. Chamberlin report that in response to 1,400 letters sent to members of the Section on Laryngology, Otology and Rhinology of the American Medical Association, 315 replies were received with records of 22 deaths from local anesthetics. All of these fatalities had occurred within two or three years, and, with the exception of three, none have been reported in the medical journals. A brief summary of these deaths is presented from which the Committee concludes as follows: (1) Deaths from the administration of local anesthetics are vastly in

excess of the number reported in the medical journals. (2) In most instances convulsions are the first indications of toxic effects; consciousness is never regained, and death ensues within a comparatively short time. (3) The customary dosage of local anesthetics varies from small amounts to very large ones. (4) There is no check on the manufacturer as to the comparative toxicity of the various batches of drugs that are placed on the market. (5) The freedom from ill effects noticed by so many who have used these drugs has made them oblivious to the likelihood of danger. (6) The presumption of the Therapeutic Research Committee of the Council on Pharmacy and Chemistry of the American Medical Association, that there are many unrecorded deaths, is thoroughly substantiated. (7) The appointment of a commission to investigate further these deaths and take action thereon is vitally necessary.

11. Presence, Absence and Location of Râles in the Prognosis of Pulmonary Tuberculosis.—Francis B. Trudeau presents an analysis of 1,000 consecutive admissions to the Trudeau Sanatorium during the years 1907 to 1913, whose condition was looked up and reported in 1918. Cases in which no râles were found, either on admission or on discharge examination, show the highest percentage of "cures." Those patients who entered the institution with râles but who lost them during their stay form nearly as favorable a group as those showing no râles at any time. In patients who entered the institution without râles but who developed them during treatment, the prognosis is much more grave than in either of the two above mentioned groups. In spite of the greater frequency and the more common findings of the tubercle bacilli in the right upper lesions as contrasted with the left upper, the prognosis is considerably more favorable in the former class of patients. Basal râles should not be diagnosed as nontuberculous too lightly, for in nearly 50 per cent. of this series, tubercle bacilli were found in the sputum, and nearly 40 per cent. of these developed apical râles during their stay in the sanatorium. The prognosis among these cases in which the râles were limited to one or both bases was not more grave than in those patients with râles over one or both upper lobes.

7. Copper in Tumors and in Normal Tissues. Charles Powell White.

2. The Milroy Lectures on Respiratory Efficiency in Relation to Health and Disease.—Martin Flack offers evidence as to the importance of respiratory efficiency based upon results obtained upon flying officers. Modern service flying, particularly in time of war, imposes great stress upon the airmen; it became important, therefore, to devise simple tests which besides helping to elucidate the causes of flying strain, would aid in the efficient selection of suitable candidates for flying. Various considerations led the writer to the point of view that in many cases of flying strain the first breakdown in the bodily system was probably in connection with the respiratory mechanisms, which became defective in working, reacted unfavorably upon the efficiency of the circulatory and nervous systems, and thereby brought out signs of cardiovascular or nervous debility. Attention is called to the correct muscular movements of breathing in massaging the abdominal contents. The descent of the diaphragm in inspiration and the contraction of the abdominal wall in expiration provide massage mechanism which plays an important part in the preservation of the tone of the smooth muscle of the abdominal contents. Constipation does not occur when a good tone of the abdominal wall is preserved. Good tone of the muscles constituting the natural abdominal belt play an important part in preserving a healthy condition of the abdominal contents. Among the special routine tests employed are those of vital capacity, breath holding and a test for expiratory force. As an endurance or fatigue test, the test of sustaining 40 mm. of mercury with the breath held has been devised. As an adjunct to this test the pulse is counted. In the fit man the rate of the pulse is not materially changed during the time the mercury is sustained; in the slightly less fit the pulse rises gradually in rate until just before the end. The average time for sustaining the column of mercury in the fit individual is from 50 to 60 seconds. The author finds that these respiratory tests afford valuable help in determining physical efficiency.

5. Nutrition and Growth on Diets Devoid of True Fats.—J. C. Drummond and Katherine H. Coward report that young rats have been grown from weaning to maturity on diets, deprived as far as possible of neutral fats, and have shown normal development and behavoir. More deaths were encountered among the animals fed on fat-free diets than among those receiving fats. It would appear that neutral fats are, from a purely physiological standpoint, dispensable constituents of a diet, provided the other food stuffs supply a sufficiency of the vitamine frequently found in association with natural fats. It is intended to ascertain whether the capacity for breeding and rearing the young is in any way inhibited by these fat-free diets.

6. A Note on the Use of Sulfarsenol in the Treatment of Congenital Syphilis.—E. Crawford and G. B. Fleming compare the results obtained in the treatment of thirty-five children with intramuscular injections of sulfarsenol and mercurial inunction with those published for kharsivan. The results suggest that the intramuscular injection of sulfarsenol is not as efficacious in producing a cure of congenital syphilis, as evidenced by the Wassermann reaction, as intravenous injection of kharsivan. Whether the virtue in the latter method lies in the drug *per se* or in the method of administration (intravenous as against intramuscular) they are at present unable to say.

7. Copper in Tumors and in Normal Tissues.—Charles Powell White has analyzed a large number of animal and vegetable substances with reference to their copper content and summarizes the results as follows: (1) Copper appears to be univesally present in the tissues of animals and plants so far as it has been looked for. (2) The known catalytic action of copper and the presence of copper in seeds, ova, and in fetal as well as in adult tissues suggest that it has a physiological significance. (3) Copper is present to a greater extent in degenerating tumors than in those which are not degenerating. This suggests either that the degeneration is associated with an increased catalytic action due to the increased amount of copper, or it may be that copper, like calcium, tends to be deposited in degenerated areas.

British Medical Journal.

October 1, 1921, No. 3170.

1. The Restoration of the Normal Cardiac Mechanism in Cases of Auricular Fibrillation by Means of Quinidine Sulphate. Alan N. Drury and C. C. Iliescu.
2. The Manner in Which Quinidine Sulphate Acts in Auricular Fibrillation. Thomas Lewis, A. N. Drury, C. C. Iliescu and A. M. Wedd.
3. Enlargement of a Splenculus to the Size of a Normal Spleen After Removal of a Ruptured Spleen Two Years Previously. W. McAdam Eccles and G. D. Freer.

1. The Restoration of the Normal Cardiac Mechanism in Cases of Auricular Fibrillation by Means of Quinidine Sulphate.—Alan N. Drury and C. C. Iliescu have treated thirteen cases of auricular fibrillation with quinidine sulphate, given in gelatin capsules by mouth, and in six cases the normal rhythm has been established, while in the remaining seven cases, although similar changes have been produced in the retardation of the auricular rate the movement persisted without break, and the rate returned, upon withdrawal of the drug, to its original level. The percentage of success obtained is of the same order as that obtained by several other workers, and the successful and unsuc-

cessful cases, as previous workers have shown, do not fall into any special clinical group either with regard to etiology, cardiac enlargement, valvular involvement, or duration of the malady. Both successful and unsuccessful cases form heterogenous groups. The drug quinidine sulphate has a very remarkable action upon the auricle, and this action is of a potent nature. For this reason alone the method of direct leads from the chest is of importance, for it gives a record of the effect of the drug upon the auricle itself; the effect on the auricle will vary considerably owing to the factors of absorption, individual tolerance, etc., and the direct leads enable the drug to be controlled.

2. The Manner in Which Quinidine Sulphate Acts in Auricular Fibrillation.—Thomas Lewis, A. N. Drury, C. C. Iliescu, and A. M. Wedd review the theory of fibrillation which they have supported in previous communications, namely, its dependence upon circus movement in the auricle which is only possible (1) if a circular path of sufficient length is available; (2) if the refractory period is sufficiently short; and (3) if the speed at which the wave moves through the muscle is sufficiently slow. In recent experiments they have found that the most striking action of quinidine upon the auricle is to lengthen the refractory period; the lengthening which occurs, when doses comparable to those used clinically are employed, amounts to 50 per cent. or more. Quinidine prolongs the refractory period of the auricle and delays the recovery of the tissue, thus rendering the gap between the crest and the wake of the circulating wave shorter and eventually abolishing it altogether; when the last event happens the abnormal action of the auricle ceases and the normal impulses are thus enabled once again to resume control. Quinidine has not only this action upon the refractory period, it has further actions. The most important of them from the present standpoint is an effect on the rate of conduction; it slows conduction in the auricle. Slowing the conduction prolongs the gap. Thus quinidine exerts two actions which are opposed to each other. It is only in those cases in which the first effect predominates over the second that the gap will close and the circus movement will terminate. In patients suffering from chronic auricular fibrillation the first effect appears to predominate in approximately 50 per cent. of the cases, for in this percentage auricular fibrillation is abolished; in the remaining 50 per cent. in whom this desired end result is not obtained it would seem as if the second effect predominates, or that the opposite effects are exerted equally. The writers utter a word of warning against the indiscriminate and uncontrolled use of this powerful remedy, inasmuch as it is a remedy of which we still have too little knowledge; it is one which, unless it is strictly controlled by frequent records of the auricular and ventricular action, is not without serious risk. A phenomenon which not uncommonly disturbs treatment is a rise in ventricular rate. This may be due to two causes, probably acting together. A fall in auricular rate is in itself sufficient to produce a lesser grade of block and a resulting rise in ventricular rate. But it is also found that quinidine has a paralyzing effect on the vagi, an action not altogether unlike, though less powerful, than that of atropine. Opposed to these actions is a direct action of the drug upon the junctional tissues. This opposed action probably moderates in some measure the rise of ventricular rate which occurs during the clinical use of quinidine in cases of auricular fibrillation.

3. Enlargement of a Splenculus to the Size of a Normal Spleen.—W. McAdam Eccles and G. D. Freer relate the history of a young man, 21 years of age, who received a violent blow over the splenic region on May 24, 1910. Symptoms developed which necessitated opening the abdomen. On examination of the spleen it was found to be torn on the inner side in the region of the hilum. Splenectomy was performed. That the actual spleen was removed is proved by the fact that it was weighed and found to be 13 ounces, a normal spleen in the adult weighing about 7 ounces. The patient had apparently contracted malaria previously to the accident, and the enlargment of the spleen may have contributed to the ease with which it was ruptured. Dr. John Gray, who assisted at the operation, writes that "the spleen was completely removed." The nurse also who assisted at the operation says she saw the spleen. The patient fully recovered. At the end of eight years he began to develop a ventral hernia at the site of the left rectus incision. On September 4, 1920, he was operated on for the repair of this ventral hernia. On opening the abdomen, five persons confirm the fact that a well-formed, normal-looking spleen was seen in the usual position. The shape, size, notch, color and consistency all appeared to be that of a normal spleen. A normal left kidney was palpated. That a splenculus may enlarge after the removal of an ordinary spleen is well known, but such an enlarged organ is rarely seen during life.

Glycemia and Graves' Disease.—Sainton and two others contribute an elaborate study of this association which has been known for half a century and has a considerable literature. This glycemia, it is claimed, is not so dependent on the diet as the ordinary type of diabetes and crises of it are said to coincide with exacerbations of hyperthyroid disease. A study of the isolated syndromes of Graves' disease and clinical diabetes is said to show that each carries a suggestion of the other; thus an ordinary diabetic may show slight evidences of hyperthyroidism, while a patient with Graves' disease may have thirst, polyuria, and other symptoms of the diabetic. The subject of Graves' disease may also exhibit a tendency to acidosis connected with anomalies of the protein metabolism. The authors have made numerous blood studies of subjects with Graves' disease, with normal controls. The technique was microchemical, the method of Folin having been used to some extent. In addition to the ordinary tests, provocative methods were used—special feeding, injection of adrenalin, hypophysin, thyroidin, etc. The results of the authors' labors seem to have been almost negative throughout. Nothing new was learned, while the doctrine of Labbé and others concerning a hybrid of diabetes and Graves' disease seems to be quite without foundation.

Ratio of Cholesterin to Other Lipoids in Cancer Patients.—Loeper, Debray, and Tonnet have calculated this ratio in 11 patients with visceral cancer. No law can be deduced from location, for both the highest and lowest ratios were in cases of gastric cancer. The variation is partly individual (?), although the larger the tumor mass and more rapid the growth-rate, the lower the ratio. Again, in the presence of a high degree of anemia it is also low. The cholesterin alone may be below normal in the blood serum, but the other lipoids are very often augmented. The ratio is obtained by dividing the figure for cholesterin by that of the other lipoids. The authors also instituted comparisons between the cholesterin in the serum and that in the tumors. In the latter the cholesterin varied from 0.6 to 4 per 1,000, while the other lipoids went as high as 14 per 1,000. In the serum the limits were, roughly, from 1 to 3 parts per 1,000 of cholesterin, and of other lipoids from 2 to 8 parts per 1,000. The problem is complicated by the fact that radiotherapy, to which most of the cases have been more or less subjected, is believed to diminish the content of cholesterin and to increase that of the blood lipoids. The authors believe that the tumor consumes cholesterin and excretes other lipoids, incidentally producing anemia.

Lumbar Puncture for the Disposal of Obstinate Syphilides.—Schreiner has made the accidental discovery that obstinate syphilitic dermatoses clear up promptly in the course of spinal tappings. The effect is much more striking in recent syphilides, for these may vanish in a day or two. But the same result has been seen in the most obstinate nonsyphilitic dermatoses, such as lichen planus and prurigo, although repeated punctures are required in the more chronic cases.—*La Presse Médicale.*

THE MANAGEMENT OF MEN. A Handbook on the Systematic Development of Morale and the Control of Human Behavior. By EDWARD L. MUNSON, Colonel, General Staff (Med. Corps.); Chief, Morale Branch, War Plans Division (Lately Brigadier General, General Staff). Prepared with the literary assistance of ARTHUR H. MILLER, Major, Coast Artillery Corps. New York: Henry Holt and Company, 1921.

ONE big interest stimulated through the agency of the war is the effort for the betterment of life for human beings by means of an advance in the morale of large bodies of men. If men in masses can be improved mentally, morally, and physically, it naturally follows that the individual man makes a big step forward in service and happiness.

The book is a treatise on the swinging forward of large groups of men toward a sane, steady, yet perfectly practical management of their life affairs. This is to be accomplished through a careful handling of both the individual and the group by those higher up in authority and power under whose control large masses of men come. The auther worked out his principles in the U. S. Army at the time of the war and has adanted them for the use of bodies of men in the industrial world. As he himself states in the opening of his book "Not only are the measures proposed correct in principle, but they have been shown to work in practice."

The basic instincts; psychological qualities; the human agents of morale control; the functioning of the morale organization; some elements of leadership; education, information, training; recreation; health and mental state; reward, punishment, delinquency; and industrial morale are some of the topics ably handled in this work.

In one chapter Colonel Munson says in substance that nothing is accomplished in his work of morale management by argument. Much more is gained by the statement of the fact to be driven home, than by the oft repeated statement of the same fact—over and over—until it is actually placed in the minds and consciousness of the men for whom it is intended. And that is the way he has written his book. He presents a certain fact, then he carries the reader on, but somehow that first fact keeps reappearing, not once but perhaps several times, nicely correlated to other facts, until, if the reader has any perception at all, he must have received the message and been convinced. The book is a product of perfect understanding of military morale. So much so that at times the reader almost feels that a company of infantry is facing him and the order given, Bang! A report of guns and over come the facts and statements and down he goes! Knocked down by the ever-direct truth shot at him.

It is a book which should not be read in a hurry. It contains too much food for thought for hasty reading since there is hardly a relation in life but has been worked out for better condition. That the writer has an intense interest in all which concerns men for their advancement is fairly breathed from every page. He puts tremendous responsibility on the shoulders of men in authority, especially the officers in the army.

GENERAL PATHOLOGY. An Introduction to the Study of Medicine, being a Discussion of the Development and Nature of Processes of Disease. By HORST OERTEL, Strathcona Professor of Pathology and Director of the Pathological Museum and Laboratories of McGill University and the Royal Victoria Hospital, Montreal, Canada. Price, $5.00. New York: Paul B. Hoeber, 1921.

THE author presents an introduction and general outline of pathology in a readable and entertaining style, which initiates the student into the subject without overpowering him with the complexity of the subject. A pleasing feature of the book, and one desirable from the educational point of view, is the outline of the historical development of present-day ideas regarding pathology, not by a recital of a sequence of events, but by showing the bearing and influence which one step of thought has exerted upon the next. The volume is divided into two parts, the first of which is devoted entirely to bacteriology, infection, immunity, predisposition, and heredity, which are discussed in a much more extensive way than is ordinarily done in textbooks on pathology. In the second part of the volume the author aims to visualize as much as possible pathological occurrences by emphasizing the anatomico-histological side from the dynamic standpoint. Pathological phenomena are presented in their general characters and grouped in categories more or less without regard to their occurrence in a particular organ, the writer's object being confined to making clear that pathological processes are physiological and chemical cell alterations and disturbed cell relations which follow common biological laws and in the majority of instances, at least, find definite anatomical expression. The book affords a refreshing departure from the steretotyped textbook on pathology, though, to use the author's words, "the spade is only handed to the reader; he must himself do the digging."

PATHOLOGIE UND THERAPIE DES HÄMOLYTISCHEN IKTERUS. Von Prof. Dr. M. MOSSE. Price, 580 marks. Halle A. S.: Carl Marhold, 1921.

THIS brochure of 50 pages is one of the "Sammlung zwangloser Abhandlungen aus dem Gebiete der Verdauungs- und Stoffwechsel-Krankheiten." The four chapters are devoted respectively to bile-formation outside the liver, hematogenous icterus, hemolytic icterus, and icterus neonatorum. The section on hemolytic icterus makes up the bulk of the book and is divided into ten subsections.

NACHKRANKHEITEN DER RUHR. Von Professor Dr. H. STRAUSS, Direktor der inneren Absheilung des Krankenhauses der jüdischen Gemeinde zu Berlin. Sammlung zwangloser Abhandlungen aus dem Gebiete der Verdauungs- und Stoffwechsel-Krankheiten. vii. Band. Heft 12. Price, 7 marks. Halle a. S.: Carl Marhold, 1921.

FOLLOWING a brief summary on dysentery are four sections on the sequelæ of the latter, dealing respectively with the nesology, symptomatology, course and treatment of these sequelæ. The latter comprise diarrheas, spastic-hyperalgetic manifestations, gastric finds, proctoscopic finds, bacteriological and serological finds, and extra intestinal complications. Treatment comprises specific, dietetic, medicamentous, endoscopic and surgical measures.

DIE PROPHYLAXE UND THERAPIE DER ENTEROPTOSE. Von Prof. Dr. LUDWIG KNAPP. Price 42 Marks. Berlin and Vienna: Urban & Schwarzenberg, 1921.

THIS volume of 118 pages begins with the prophylaxis of enteroptosis, which occupies 12 pages. Under treatment are considered the physical, neurological, conservative and operative forms. There is a special chapter on the separate ptoses and another on prolapse of the pelvic organs. Under surgery, operations for the separate ptoses are described. There are no illustrations, an omission difficult to understand in a work of this scope. The author has no comment to make on this drawback.

FUNDAMENTALS OF BACTERIOLOGY. By CHARLES BRADFIELD MORREY, B.A., M.D., Professor of Bacteriology and Head of the Department in the Ohio State University, Columbus, Ohio. Second Edition, thoroughly Revised, and Illustrated with 171 Engravings and Six Plates. Philadelphia and New York: Lee & Febiger.

IN the second edition of this textbook the original method of presentation is adhered to, which aims to give to the individual instructor full liberty to expand on topics in which he is especially interested. The author makes no attempt to produce an encyclopedic work, but rather to give a comprehensive grasp of the subject and to furnish a background for later work along special lines. It is therefore not adapted to meet all the needs of the medical student. Neither does it go into the minutiae of laboratory detail required by the advanced student or laboratory worker. The subject, however, is covered in a general way and recent advances in the science of bacteriology have been incorporated in this edition. The system of classification of the Society of American Bacteriologists is used throughout the text, and their Key to the Genera of Bacteria has been added.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 6, 1921.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

The Application of Pallidum Infections in the Rabbit to the Study of Problems of Human Syphilis. With Lantern Demonstration.—DR. WADE H. BROWN of the Rockefeller Institute for Medical Research presented this paper, from the point of view of the conduct of experiments and the interpretation of their results, emphasizing the joint responsibility which rested upon the clinician and the laboratory investigator in endeavoring to utilize this means for the solution of problems of human syphilis. He pointed out that a great many of the problems of experimental syphilis were problems of clinical medicine and that the benefits which might be derived from such investigations would depend very largely upon the ability of both the clinician and the laboratory investigator to judge of the fitness of the methods employed and of the significance to be attached to the results. The first essential in meeting these requirements was a familiarity with the characteristic features of the animal as well as the human infection. The material used as a basis for the development of this subject was drawn from two lines of investigation which had been carried out at the Rockefeller Institute by Dr. Brown and Dr. Pearce. The first of these consisted of a clinical study of the infection produced in the rabbit extending over a number of years, the purpose of which was to supply a detailed and systematic knowledge of the experimental infection to be used as a basis for the investigation of specific problems. The second phase of the work dealt with selected problems of varying degrees of complexity in the presentation of which the subjects of the planning and execution of experiments and the interpretation of results were considered. The disease produced in the rabbit by virulent strains of *Treponema pallidum* was described as one which began with a satellite adenitis, followed by the development of a primary lesion, a general lymphadenitis, and in certain instances by the development of a variety of lesions in the bones, the skin and mucous membranes, and the eyes—corresponding in general with manifestations of disease which occurred in man during the socalled primary and secondary stages of syphilis. These features of the animal infection were illustrated by lantern slides. Attention was called to the fact that thus far, visceral lesions and tertiary manifestations of disease had been very rare and that those observed were usually granulomatous processes involving the myocardium or degeneration and necrosis of the middle coat of the aorta, examples of which were shown. The absence of this class of lesions was attributed to the degree of virulence thus far attained by laboratory strains of *Treponema pallidum* on the one hand and on the other to the prompt and vigorous reaction exhibited by the rabbit. Among the features of the animal infection which were regarded as of especial significance to the investigator, mention was made of: (1) The time and frequency of occurrence of satellite lymphadenitis and of general lymphadenitis. (2) The relapsing course of both the infection and the disease. (3) The pronounced character of primary lesions as compared with those of man. (4) The low incidence of generalized disease in certain forms of infection. (5) Circumstances which favored the occurrence of generalized disease. (6) Variations in the character of the disease presented: (*a*) In different animals of the same series. (*b*) In response to the use of different experimental conditions. (7) The constancy of the occurrence of metastatic lesions in the testicles and the frequency of their occurrence in the scrotum. Lack of knowledge of such conditions as these had constituted a serious handicap to the work of earlier investigators and had at times led to results which were difficult or impossible of interpretation. Reinoculation experiments in the testicles or scrotum were cited as examples of instances where confusion had been introduced through unfortunate selection of a method of experimentation.

Turning to the investigation of concrete problems, it was pointed out that the permanent part of any investigation was represented by the facts established—that before any interpretation or generalization could be of value, one must be assured of the validity of the facts upon which it rested and that this implied the possession of a sufficiently detailed and systematic knowledge of a subject to enable one to judge of the fitness of the methods employed in a given instance and the reliability of the criteria used for the determination of results. A series of experiments of varying degrees of complexity was then reported, especial attention being given to the selection of methods of investigation and the means employed for the determination of results. The first series of experiments described dealt mainly with the dissemination and localization of spirochetes in infected animals as determined by subinoculation of normal animals with emulsions of lymphoid tissues taken at various intervals of time after inoculation. From these experiments, it was found that invasion of the lymphoid system invariably occurred within the first 48 hours after inoculation and that infection persisted indefinitely, being demonstrable in all animals examined at any time subsequent to inoculation, the longest interval being 4 years and 9 months. It was pointed out that the procedure followed in these experiments was extremely simple and was dictated largely by a knowledge of the clinical course of the disease. The early appearance of a satellite lymphadenitis, the constant occurrence of general lymphadenitis and the persistence of abnormalities in the superficial lymph nodes after all other manifestations of disease had disappeared pointed unmistakably to this system of tissues as the point of attack. The use of tissue implants instead of fluid emulsions and the selection of the scrotum as the site for the original inoculation were in themselves important details in that the possibility of driving the spirochetes into vascular channels by the injection of a fluid emulsion was overcome and it was possible to correlate clinical alterations in the inguinal nodes with the reaction at the site of inoculation on the one hand and with the infectivity of the node on the other. Similar experiments were carried out on the blood for the purpose of determining the relation existing between the socalled blood stream invasion and the evolution of the disease. The method of experimentation employed in this case was somewhat different. The animals studied were inoculated in the testicles instead of the scrotum since this mode of inoculation was known to produce infections of a much more uniform character and with sharper delimitation of successive phases of the reaction. By properly timing the examinations, it had been possible to show, as in the case of the lymph nodes, that spirochetes entered the blood stream before the primary lesions were recognizable. Moreover, the infectivity of the blood increased with the progress of the local infection and declined during periods of regression and was eventually lost with the healing of active lesions, differing in this respect from the lymph nodes. A second group of experiments concerned the possibilities of infection through normal mucous membranes. It was stated that the first report of an infection produced by the application of a fluid emulsion to an apparently normal mucous membrane was published by Reasoner in 1914. Eight animals were used in these experiments and one of them developed a characteristic chancre-like lesion in which spirochetes were demonstrated. At that time, no other clinical signs of infection were known so that some uncertainty remained as to what occurred in the other animals of the series. Experiments of the same character were carried out by Brown and Pearce on a number of animals using three strains of spirochetes. Male rabbits were used throughout; the majority of them were inoculated by the instillation of 0.05 c.c. of a spirochete emulsion into the sheath; others were inoculated by the introduction of the same dose of organisms into the conjunctival sac. These experiments were planned with a view to using criteria of infection other than the development of a chancre. Thus male rabbits were used on account of the high incidence of metastatic lesions in the testicles and scrotum while the sheath was chosen as the site of inoculation in order to utilize inguinal adenitis as an additional aid in the determination of results. The introduction of these features

into the experiments proved to be of great value. In all instances enlargement and induration of the inguinal nodes occurred within 1 to 5 days after the application of the virus to the sheath. The majority of the animals subsequently developed lesions on the penis but these were usually quite small and differed in general appearance from lesions produced by mechanical inoculation. Frequently the first lesions were in the scrotum or testicle and in some instances these were the only lesions, there being no visible lesion on the parts where the virus was applied. A final series of experiments dealing with modification of the clinical course of disease by the use of experimental methods was cited as an example of the possibilities for investigating complex phenomena such as those which determine the usual course of the infection, the importance of a working hypothesis and the ability to select and to use methods of investigation which would yield cleancut results. The experiments reported were based upon the conception of the existence of an intimate relationship between all processes of reaction and disease of such a nature that a modification of the reaction occurring at one stage of the infection would be reflected in the subsequent course of the disease. It was shown how this could be demonstrated by varying the conditions under which the infection was initiated, or by suppressing defensive reactions at various stages in the progress of the disease. In speaking of these experiments, reference was made to the fact that three fundamental types of reaction or disease occurred in the rabbit: An average or usual type characterized by a vigorous local reaction with slight manifestations of generalized disease, a mild but prolonged local reaction followed by frequent generalized lesions presenting the same characteristics, and a malignant type. This form of reaction was described as anomalous in that the initial or primary reaction was the most vigorous of all but instead of resulting in a prompt termination of the disease as might be expected, the local lesions assumed a distractive character and were followed by marked and widespread manifestations of generalized disease. It was believed that these peculiarities pointed to the existence of distinct qualitative and quantitative differences in the defensive mechanism of individual animals.

In concluding, Dr. Brown said that the discussion of these few problems would serve to indicate the scope of investigations which could be undertaken and something of the conditions which must be met in the prosecution of experiments of this kind. Conditions which were regarded as of prime importance in the conduct of experiments or in the interpretation of results included: (1) A detailed and systematic knowledge of the experimental infection. (2) The ability to observe and to measure phenomena. (3) The ability to judge of the fitness of methods employed and of when and how successive stages of the experiments should be carried out. (4) The ability to maintain a clear cut distinction between the facts derived from an experiment and one's interpretation of these facts. (5) A point of view unprejudiced by previous work or by current conceptions. (6) Finally, an equation for the comparison of phenomena of the human and of the animal infection and for the translation of the phenomena of one into terms of the other. He then emphasized the necessity for the coordination of clinical and experimental points of view in an endeavor to obtain a proper orientation of experimental investigations and in determining their significance to human syphilis.

Dr. WALTER J. HIGHMAN said that the fact that others who were to have discussed the paper were absent had placed rather more of a burden upon him than he had expected to shoulder, especially in view of the fact that Dr. Brown had requested that a clinician interpret the facts he had presented. This was exceedingly difficult inasmuch as it was hard for the clinician intelligently to interpret the clinical manifestations of syphilis even in the human being. The golden era in respect to clinical syphilis began with the work of Schaudinn in 1905 and terminated in 1911 when Ehrlich started us on an era of hyperenthusiasm which subsequent experience had not justified. The second period was the one in which we found ourselves at the present time and was represented by the efforts of Dr. Brown to elucidate, albeit by animal experimentation, what we were at a loss to explain in the human being. Many of the problems of syphilis were difficult to explain because no man saw enough cases through the entire course of the disease. A physician saw primary syphilis in one group, secondary syphilis in another group, and tertiary in another, but he did not see one patient from the time of the infection until he died or was cured. So we had not in human beings the advantages of the laboratory. The differences between syphilis in the rabbit and in the human being were clearly brought out by Dr. Brown but he should hesitate to draw an analogy between syphilis in the rabbit and in the human being. He had hoped that we would get something from the experimental work that would enable us to face the problem of syphilis with optimism. He had thought it might be possible to perform experiments which would show the results in treated and untreated cases followed to the end, to make comparisons between treated and untreated syphilis in alcoholics, and likewise the relation of tobacco to syphilis. He thought it might be possible to demonstrate experimentally the results of a combination of syphilis and morphine. He understood that the Chinese while a highly syphilitic race rarely had syphilis of the central nervous system. Perhaps opium dulled the sensitivity of the central nervous system of the Oriental. Dr. Highman said he frankly and thoroughly coincided with Dr. Brown's point of view with reference to the interpretation of facts and the attempt to eliminate the subjective on the part of the observer, and all he had attempted to do was to point out a few of the questions upon which experimental work might throw light; he could not say whether or not there was anything in the experimental work presented that was of practical value to the clinician.

Dr. DAVID JOHN KALISKI said he thought Dr. Brown's attitude concerning the relationship between animal syphilis and human syphilis was correct. He did not believe we were justified in drawing conclusions at this time as to a definite relationship existing between the two. He thought this fact would be brought home to us more clearly if we recalled that as early as 1914 Arzt and Kerl, and before them some English workers, showed that in normal rabbits there existed an infection with spirochetes, and definite lesions were present which, while not the same as those shown by Dr. Brown in rabbits, were nevertheless lesions of a scaly or slightly ulcerating type; and in these lesions one could find spirochetes which morphologically could not be differentiated from *Spirochæta pallida*. These organisms morphologically identical with *Spirochæta pallida* had been found in regional lymph nodes also and in a number of instances similar lesions had been inoculated in other sites. This showed how difficult it was to draw conclusions from experiments with rabbits infected with human syphilis. The work of Arzt and Kerl had been again taken up by Jacobsthal and Tomascewski, and these facts had been confirmed, and so it seemed to him that, strict as Dr. Brown was, yet there was in these experiments a disturbing factor. It had been found that in normal rabbits as many as 25 to 35 per cent. of certain strains had skin and genital lesions resembling closely those produced by placing the virus of syphilis on the skin; and not only did these lesions occur spontaneously in normal rabbits, but the organisms could be transmitted by coitus. These facts injected a disturbing factor into the question of the relationship between experimental syphilis and syphilis in man which demanded immediate clarification.

Dr. BOLESLAW LAPOWSKI stated that the clinician expected entirely different results from experimental work than did the laboratory man, but Dr. Brown was not to blame for that, for in his writings he explained his mode of action. He had planned out two phases of investigation. The first was to learn the manifestations of syphilis in animals, especially rabbits, and when he was acquainted with the manifestations of syphilis in them he planned to take up the second step and to compare syphilis in rabbits to syphilis in human beings. He had reached the first stage satisfactorily. There was no better work on rabbit syphilis than that which he had carried out. The facts were there. The interpretation of facts was sometimes very difficult but useful, since out of a clash of opinion ensues progress. The clinician would ask the experimenter to confirm

certain things that he himself must wait a lifetime to determine, that was whether certain procedures employed in the treatment of syphilis were satisfactory. We had been led to expect a new era when syphilis could be cured in six months; this must be settled experimentally. If the clinician saw a patient present a very small, suspicious lesion and he made a tentative diagnosis of syphilis and treated it for months and watched for a positive Wassermann or clinical manifestation, he might have to wait a lifetime to determine whether the patient had syphilis, because superinfection was not a proof and reinfection in the sense to prove a previous cure did not happen. Again, men used different methods in treating syphilis. One used salvarsan and mercury; another got the same results with salvarsan alone. If a man used a certain method and failed we said his method was wrong. Those questions had to be taken up experimentally. Another question was whether it was advisable to subdue secondary manifestations. Do secondary manifestations help the patient to overcome the tertiary form of the disease? That was a most important question. Dr. Brown passed that question over too quickly. He said if we suppressed the primary lesion syphilis might appear in the tertiary form, and then came Dr. Kaliski, who said that syphilis in the rabbit might not be syphilis at all. If Dr. Brown would show the history of that rabbit which he observed for five years, from the time of infection through the five years of observations, it would be of great value. Some told us in describing syphilis in rabbits that there were no relapses in rabbit syphilis; while relapses in human syphilis were characteristics par excellence of human syphilis. The next question was how did the Wassermann behave in inoculated rabbits? Was the Wassermann changed by treatment into a negative and then returned to a positive? These were some of the points not worked out. Dr. Lapowski said the subject was very large and presented many problems which must be worked out experimentally, but time prevented him from going into them.

Dr. Brown, in closing the discussion, said that in outlining the topics for presentation they had started with problems of a simple character with the intention of going on to others of a more complex character and ultimately to some of the questions propounded by Dr. Lapowski, but that time had not permitted. Taking the questions in order, Dr. Highman had indicated certain problems that he would like to have solved. While they had not investigated problems of precisely that nature, he thought that they were well within the range of present possibilities. The point raised by Dr. Kaliski and by Dr. Lapowski as to the occurrence of a natural infection in the rabbit which might be confused with a pallidum infection was attracting a great deal of attention at the present time. This infection was first described by Arzt and Kerl in 1914. Since then it has been investigated by Schereschewsky and by Lersey, Dosquet, and Kuezynski in Berlin, by Jacobsthal in Hamburg, by Levaditi, Marie, and Isaicu at the Pasteur Institute, and by Klarenbeck at Utrecht. Opinions differed as to the significance of this infection. The organism itself was either morphologically identical with *Treponema pallidum* or resembled it so closely that the two were very difficult to differentiate. The manifestations of disease which had been described were usually but not always confined to the region of the genitalia, and although the organism had been recovered from lymph nodes and lesions of the skin had been observed on various parts of the body, it was still uncertain whether the infection was local or systemic in nature. As to the lesions themselves, two types of processes had been described: One in which there was a large element of acute inflammatory reaction and the other an infiltrative process of an indifferent type associated with desquamation or exfoliation of epithelium. These lesions had been regarded by some as indistinguishable from those attributed to *Treponema pallidum*. There were points of resemblances between certain of these lesions and some of those obtained with freshly isolated strains of *Treponema pallidum*, but no one familiar with the pallidum infection would be likely to confuse the disease thus far described with that produced by highly virulent strains of *Treponema pallidum*. Nevertheless, opinions as to the relation existing between these two infections should be reserved until further information was available. Referring to the series of questions raised by Dr. Lapowski, Dr. Brown said that he thought that animals could be used at the present time to investigate precisely the group of problems suggested. He pointed out that the methods originally employed for conducting therapeutic investigations were subject to serious limitations in that they were aimed entirely at a determination of spirocheticidal action as indicated by the ability of a drug to cause a disappearance of spirochetes from lesions and to induce healing. Unfortunately, there was no means of determining, at that time, whether the spirocheticidal action of a drug was actual or only apparent. These methods were developed about Ehrlich's conception of a spirocheticidal therapy or the use of a drug which was capable in itself of destroying the spirochetes and thus accomplishing the cure of the infection. If this could be done with certainty and with safety, one might disregard other elements of therapeutic action. Experience had shown, however, that the limited treatment which so many patients received frequently failed of sterilization. The old question, therefore, arose as to the advisability of interfering with the development of a protective reaction on the part of the patient by the suppression of secondary lesions, as stated by Dr. Lapowski, or the use of therapeutic measures intended to reinforce the native resistance of the patient. These were pertinent questions. Formerly they could not be attacked experimentally, but progress in our knowledge of the animal infection has opened up a wide field for therapeutic investigation, including more accurate determination of spirocheticidal action as well as the influence which drugs might exert in other directions. Time did not permit the consideration of other questions.

SECTION ON MEDICINE.

Stated Meeting, Held April 19, 1921.

DR SAMUEL BRADBURY IN THE CHAIR.

Report of a Case of Paralysis of the Left Vocal Cord Associated with a Cardiac Lesion of Obscure Nature.—Dr. BERTON LATTIN presented this patient, a Hebrew, male, nineteen years of age, an office clerk, who was first seen in the Post-Graduate Cardiac Clinic, February 4, 1921. To the best of his knowledge the patient was in good health up to the age of eleven years, save for diphtheria at eight years with no complications. He had never suffered tonsillitis, rheumatism, chorea, or scarlet fever. He did not use alcohol or tobacco. At about eleven years of age he first noted shortness of breath on exertion. A physician whom he consulted stated that his heart was "strained a little," apparently noting no organic defect. The disability was of mild degree, the boy continuing school up to the age of fifteen. In his last year and a half of school, in high school, he did the usual calisthenics. These exercises made him conscious that his heart was acting very rapidly. About eighteen months ago the boy first noted hoarseness, which seemed to have started suddenly. This was continued up to the present time, apparently varying in degree. During the past year the shortness of breath had become somewhat more marked. On four or five occasions he had coughed up small amounts of blood. There had been no edema. He was a rather stout, plethoric boy, weighing 146 pounds. The pupils were equal and reacted normally. There was paralysis of the left vocal cord. Examination of the heart showed the apex in the fifth space, 9 cm. to the left; the right border 5 cm. out in third space. In the second, third, and fourth spaces to the left of the sternum, that was, over the right ventricle, there was felt a vigorous heaving impulse. In the second space this impulse was palpable for about 6 cm. to the left of the midline. Over this area was felt a sharp shock, corresponding to the closure of the pulmonary semilunar valve. No murmurs were heard at the apex or base. The second pulmonic sound was greatly accentuated. At the apex was felt a galloped rhythm, which was regular. The rate had varied under observation from 96 to 140. Mild exercise caused marked tachycardia, dyspnea, and tendency to cyanosis. The blood pressure was systolic 114

and diastolic 80. The electrocardiogram showed right ventricular preponderance, but no other abnormality. The teleroentgenogram showed moderate left ventricular hypertrophy. The transverse diameter was 15 cm. The right auricle seemed normal. In the upper part of the left contour was a prominent bulge extending about 6 cm. to the left of the midline. It was impossible to separate the aortic arch from the pulmonary artery in this prominence. Fluoroscopic examination seemed to show the pulsation of a dilated left auricle in this region. The correspondence of this bulge to the palpable impulse in the second space made it seem probable that it was in part a dilated pulmonary artery. The nature of this boy's heart disease was not self-evident. The assumption of mitral stenosis would readily explain the history of hemoptysis, the right ventricular hypertrophy, and the apparent dilatation of the left auricle. Paralysis of the left recurrent laryngeal nerve had been noted not infrequently associated with mitral stenosis. However, no murmurs were present. Moreover, the roentgenographic shadow did not show the characteristic globular heart of mitral stenosis. The possibility of a congenital defect must therefore be considered. A certain proportion of these defects, as was well known, gave no murmurs. The bulge to the left in the second space might suggest a patent ductus Botali with consequent dilated pulmonary artery. This lesion rarely existed alone. Patent ductus had been described as associated with recurrent laryngeal pressure paralysis. It was conceivable that there was in this case a shifting of the aorta to the right, but this was idle speculation. Evidently at the place where the recurrent laryngeal nerve hooked under the aortic arch, just external to the ligamentum arteriosum, there was some structure which was crowding the nerve against the aorta.

Dr. LIBMAN said that he also was not convinced that this patient was suffering from mitral stenosis. One thing, however, was apparent, and that was that there was a dilatation of the pulmonary artery. Dilatations of the pulmonary artery were much more frequent than was generally believed to be the case. The condition could occur with atherosclerosis of the pulmonary artery (whether syphilitic or not), mitral stenosis, and the open ductus arteriosus. Compression of the pulmonary artery beyond the conus, due usually to neoplasm or adhesions, could cause dilatation of the pulmonary artery. In such cases a systolic murmur was usually heard to the right of the sternum, whereas in other forms of the disease the murmur was heard to the left of the sternum. Apart from these forms of the disease and apart from the occurrence of dilatation due to infection of the wall of the vessel, there occurred cases which for the present could only be called "idiopathic dilatation of the pulmonary artery." Dr. Libman said that he had seen two cases of this type within the past few years. Paralysis of the recurrent laryngeal nerves occurred in a number of intrathoracic diseases. The most common cause of such a condition in cardiovascular types of the disease was aneurysm. The paralysis was usually unilateral, but could be bilateral if the aneurysm of the aorta were very large, or if the subclavians and the innominate artery were involved in the disease. Mitral stenosis had been found as a cause of paralysis of the left recurrent laryngeal nerve in a number of cases. There was a number of explanations of this condition. It could occur due to compression by the dilated auricle, or to clamping of the auricular appendage between the aorta and the pulmonary artery. In one case there was a peculiar distortion of the heart which resulted in the pulmonary artery being drawn over in such a position as to compress the nerve. In cases of open ductus arteriosus, a paralysis of the nerve had occasionally been found. The first case had been described by Schroetter, and the second by Dr. Libman himself. The compression of the nerve in such cases was very easy to understand, because it passes around the aorta exactly at the position of the ductus. In pericarditis, recurrent paralysis was also found at times. In fact, in one case, there was present a bilateral recurrent laryngeal paralysis with complete recovery after the pericarditis had subsided. The paralysis of the nerves in these various conditions might be due simply to direct compression of the nerve, or it might be due to neuritis. In the latter instance, the inflammatory process could spread up into the vagus nerve itself and then additional remarkable symptoms might occur. It was possible that certain symptoms which occurred in cases of mitral stenosis might be due to pressure on the nerve, even if the nerve were not completely paralyzed. This might be the explanation of certain forms of violent coughing associated with mitral stenosis in the absence of evidence of abnormalities in the lungs. It was important to remember that hoarseness and cough might occur in cardiac disease, especially in mitral stenosis, due to inflammatory conditions in the false vocal cords. In some cases the false vocal cords prolapsed partly or completely over the true vocal cords, and the symptoms could then resemble those present in cases of paralysis of the recurrent laryngeal nerve. Such a condition was usually termed ptosis of the false vocal cords or prolapse of the ventricle of Morgagni. Dr. Libman brought with him a specimen of a larynx in order to demonstrate a simple method of determining whether a recurrent laryngeal paralysis had been present or not. Sometimes it was very difficult to dissect out the nerve and at times it would destroy the value of the specimen if such dissection were carried out. If a recurrent laryngeal paralysis had been present, one could often determine that by looking at the back of the larynx, because one would find that the posterior cricoarytenoid muscle on the paralyzed side was atrophic or fatty, or both.

Restoration of the Normal Cardiac Mechanism in Auricular Fibrillation by Quinidine.—Dr. ROBERT L. LEVY presented this preliminary report, in which he said that during the past three years reports of 101 cases of auricular fibrillation treated with quinidine had appeared in the foreign literature; in 59, or 58.4 per cent., the normal rhythm was restored. The duration of the effect had usually been short, from a few days to a month. The usual dosage employed had been 0.4 gm. by mouth three times daily before meals, or, less commonly, 0.2 gm. five times a day. Regularization of the rhythm had occurred, for the most part, on the second or third day of treatment. Up to the present time quinidine had been administered by mouth, in gelatine capsules, to four patients in the hospital of the Rockefeller Institute. These patients had been under observation prior to treatment for periods ranging from one month to one and a half years, and were known to have been fibrillating for at least these lengths of time. On the days on which the quinidine was given electrocardiograms were made every one or two hours and were taken several times daily thereafter. In two cases a normal sinus rhythm was restored. In one of these auricular flutter intervened between fibrillation and the normal rhythm; in the other an intermediary transitional mechanism, not sufficiently regular to be classed as flutter, was recorded. In the third patient a transient auricular flutter of only a few hours' duration was followed by a return to fibrillation. In the fourth case there was a temporary increase in the heart rate without alteration of mechanism. In this patient complaint of headache and palpitation together with the appearance of occasional premature ventricular contractions induced discontinuation of the drug. The detailed records of these cases were presented. Dr. Levy stated that it was evident from a survey of the literature, as well as from observations on this small group of cases, that the factors which determined the success or failure of quinidine in altering the mechanism of the heart were not clear. They had been led to give the doses at more frequent intervals than had been recommended in the first two cases for two reasons: (1) because it was noted in the two unsuccessfully treated patients the effects induced by a given amount of the drug, as evidenced by the tachycardia and changes in the electrocardiogram, tended to disappear in the course of two to four hours; (2) because Wiechmann had shown that the greater the fractionation of the dose the greater the amount of quinidine excreted. To achieve optimal therapeutic effects it seemed reasonable, at least for the present, to administer as much of the drug in as short a period of time as was consistent with the factor of safety of toxicity. Further work on the subject was in progress.

Dr. B. S. OPPENHEIMER said that this presentation by Dr. Levy was the first which had appeared from America or Great Britain on the subject of the use of quini-

dine, and it would stimulate every one interested in cardiac arrhythmias. In view of the fact that quinidine would probably prove a valuable addition to digitalis in the treatment of auricular fibrillation, and would be used extensively, it should be emphasized that quinidine was not an indifferent substance. Dr. Hubert Mann and the speaker had had only a small experience with it,—so limited indeed that they would just mention individual cases. In one case of impure auricular flutter, the flutter became pure after quinidine. In another instance, premature beats of ventricular origin disappeared after the administration of 21 grams of quinidine, but premature beats of auricular origin appeared. A long standing, end-stage case of auricular fibrillation continued to fibrillate, but the patient, a physician, had insisted on taking a single daily dose because he experienced less palpitation when taking the drug. Finally a woman with premature beats of ventricular origin was given three doses of 0.2 of a gram each. She suffered so much from headache, flushing, burning of the face, palpitation, and weakness that she discontinued the medicine; in twenty-four hours these symptoms had disappeared. Dr. Levy had brought up the question, among others, as to the type of case in which success with quinidine was to be anticipated. Benjamin and v. Kapff had recently reported 24 cases of fibrillation with interruption by quinidine in 18. Quinidine was effective in some cases, and failed in others, in all three groups of cases with auricular fibrillation which they studied namely, auricular fibrillation associated with (1) valvular disease, (2) arteriosclerosis, (3) thyreotoxic conditions. Finally it would be very helpful in arriving at definite conclusions if the eight or ten hospitals in Greater New York which had the electrocardiographic facilities would work intensively on the subject, under some common plan and report results in the fall.

Dr. CARY EGGLESTON said that many thoughts arose in connection with this interesting series of cases. The literature now included some 100 cases of auricular fibrillation treated with quinidine. It would seem that not only did we not know the cause of the altered mechanism in fibrillation, but we did not know anything about the mechanism by which quinidine and the cinchona alkaloids acted, except that they caused an initial stimulation of all voluntary as well as involuntary muscles, and later a depression. This idea was brought out by Dr. Levy when he spoke of the increase in the number of premature contractions and the appearance of ventricular premature contractions, probably indicative of heightened irritability which was followed by depression. While it had been shown that it was possible to change auricular fibrillation to a normal mechanism, the striking feature in all these cases was that the fibrillation was resumed in a variable period of time. The question therefore whether one could continue to give sufficient amounts of quinidine to maintain a normal rhythm when once established without producing toxic effects remained to be determined. While Dr. Oppenheimer's suggestion was excellent that all who had the facilities should put this matter to a test, Dr. Eggleston thought that a word of warning should be uttered, namely, that merely because the drug had been shown to possess a marvellous capacity to alter the rhythm of a fibrillating heart to normal, recognized methods of treatment should not be abandoned. He therefore would like to emphasize the point that Dr. Oppenheimer had made that the further detailed observations necessary should be made only under conditions that permitted adequate control of the patient and the observations so as to study the duration and persistence of the reestablished normal rhythm. He did not believe this could be done under any conditions except those obtainable in a hospital where the patient could be subjected to minute observation at frequent intervals by means of the electrocardiograph. The present knowledge of this subject was not yet in a stage where this drug should be regarded as available for general clinical use. In closing, Dr. Eggleston said he felt that they owed Dr. Levy a debt for bringing the subject to attention with a view of determining the value of quinidine.

Dr. HAROLD E. B. PARDEE said that he wished to second Dr. Eggleston's statement that we owed a great debt to Dr. Levy for undertaking this pioneer investigation in this country. He was especially glad that a drug had been found that was so relatively free from danger in administration. In regard to the question whether quinidine acted as a stimulant or as a depressant, he was inclined to believe that it was a stimulant because of certain experimental work. Rothberger and Winterberg had long ago pointed out that it was possible to convert auricular fibrillation into auricular flutter by stimulation of the accelerator nerves in the dog. Moreover, auricular fibrillation could be converted into normal rhythm by the same procedure. In 1916 it had occurred to Dr. Pardee that it might be possible to convert auricular fibrillation to normal rhythm in human patients by giving atropine to cut off the influence of the vagus, and then adrenalin intravenously to supply the necessary stimulation of the accelerator system. They found this impossible however if the vagi were stimulated at the same time. He had done this in only three patients, but in one of them the rhythm had returned to normal fifty-five minutes after the administration of the adrenalin. Atropine sulphate was used in doses of $\frac{1}{50}$ grain and the adrenalin in 15 minim doses of the 1:1000 solution of adrenalin chlorid. This work has not been continued because of lack of time and because it was not thought likely that these patients would continue with the normal rhythm even though they should be returned to normal rhythm for a time. Auricular fibrillation probably resulted from a pathological change in the muscle of the auricles, and since this sort of medication would only have a temporary effect, auricular fibrillation would probably reappear. So far as the condition of the patient was concerned he did not feel sure that it would always be desirable to convert auricular fibrillation into normal rhythm, for we were able in the presence of fibrillation to keep the heart rate slowed by the proper use of digitalis, while when normal rhythm was present this was not always possible. He thought that it would be a very desirable thing if we could find a drug that would convert normal rhythm into auricular fibrillation, to be used in just such cases as this, when the rate could not otherwise be slowed. With this and with quinidine we should be prepared for any emergency. He felt that very valuable results would be obtained by Dr. Levy in continuing with this study.

Dr. ROBERT H. HALSEY said it was most important for physicians to recognize the value of these observations. If observations, such as these Dr. Levy reported, were considered by a group of men who were equipped to work on the problem, it would be a very great help in evaluating the procedure and determining what were the indications for the use of quinidine. When and what cases should have the attempt made to restore sequential rhythm and when was it wise to depart from the usual method of controlling the rapid, irregular ventricle with digitalis? In the past some cases of fibrillation under digitalis therapy ceased to be irregular and normal rhythm returned, so, it might be, the heart muscle had an inherent capacity to return to normal. Quinidine seemed to increase the possibility to an even chance. Still, considering everything said, it seemed we would have to await further observations before we knew what change to expect and what was to be done if any ill effects were produced by the drug.

Dr. LEVY, in closing the discussion, said there were two points that he would like to mention. First, in several cases in which larger doses of quinidine were given, premature contractions of ventricular origin were observed. In one instance, ventricular tachycardia of short duration occurred. For the present, therefore, the drug should be given cautiously and under adequate electrocardiographic control. A second point to be emphasized was that the use of digitalis in auricular fibrillation should not be abandoned. It was not yet clear whether, after restoration of the normal rhythm by quinidine, the function of the myocardium was improved. Observations of venous pressure and of vital capacity were being made, in addition to the usual clinical examinations, in the hope of throwing some light on this point. Quinidine treatment must still be regarded as being in the experimental stage, and a final estimate of the value of the drug as a therapeutic agent must be deferred until a large clinical material has been critically examined.

Study of the Effects of the Sippy Treatment of Pep-

tic Ulcer.—Dr. H. F. SHATTUCK read this paper, which was illustrated by lantern slides. He stated that a more accurate title of his paper would be "A Study of the Early Effects of the Sippy Method of Treatment of Peptic Ulcer." For the past two years the Sippy method had been used in the Post-Graduate Hospital and an attempt had been made to follow and observe these patients for as long a period as possible. The present report consisted in a study of the clinical symptoms and findings in 28 cases, under observation for periods ranging from three to twenty-three months. While this period was not sufficiently long to enable one to draw final conclusions the results were of sufficient interest to be reported. All of these cases gave a definite history of peptic ulcer and definite *x*-ray evidence. Cases in which the ulcer was complicated by other serious disease were excluded from the series; also cases that did not have a preliminary observation of three weeks were omitted. Of these 28 cases 22 had remained symptom free since the beginning of treatment. Of 11 cases followed for from one to two years 9 had remained entirely well and one was partially well. Of 17 cases studied with the Ewald meal it was found that there was no reduction in the gastric acidity but they all remained free of symptoms. Some cases with persistent hypersecretion were rendered symptom free. Six of the 28 cases showed occult blood and in all of these it disappeared after three weeks' treatment. In some of the cases following treatment there were visible changes in the *x*-ray findings. Dr. Shattuck said his object was not to advocate medical treatment in general or the Sippy treatment in particular but merely to report some of the effects of the Sippy treatment. As none of these successfully treated patients were submitted to surgery there was, of course, no way of knowing if there was an error of diagnosis, and it was also known that in some instances there were long periods of remission, so that it might be necessary to follow these cases for a much longer period before one could reach conclusions. He thought, however, that by this method of study one might come to a better understanding of the value of the various medical and surgical procedures employed in the treatment of peptic ulcer.

Dr. R. L. HUTTON stated that the difficulties in carrying out an accurate study as to the effects of medical treatment in peptic ulcer were quite enormous. In the first place there was the matter of getting a sufficient number of cases to warrant one in drawing any deductions. Then there was the question of following up the cases. The hospital cases were easier to follow in a way, but private patients with the intelligence to cooperate and with the economic ability to follow out the dietetic requirements and to live within the hygienic limitations prescribed were more satisfactory, and this made the conclusions more justifiable. Furthermore, it took a good many years before one reached the point where it was safe to draw conclusions. Then there was the question of determining just what happened to the lesions under any form of treatment, in view of the fact that we had such uncertain methods of determining what took place. Then there was the difficulty in determining the relationship between the symptomatic improvement and the improvement or lack of improvement in the condition as shown by the *x*-ray and other tests. In spite of all these difficulties the greatest hope of reaching reliable conclusions lay in such work as Dr. Shattuck had presented. Reports of large numbers of cases over many years and comparing the results of the Sippy treatment with those obtained by other methods of treatment, medical and surgical, checking up with operative and autopsy findings, ought eventually, to show which was the most valuable method.

Renal Tests for Ambulant Patients.—Dr. H. O. MOSENTHAL made this presentation in which he said that he had been working on tests for renal function in ambulatory patients and he believed we could tell more about kidney function from tests made when the patients were taking normal amounts of food and living in the way they were accustomed to than when they were under artificial conditions. With the tests of renal function generally performed at present artificial standards were imposed upon the patient. There was a tendency to take the blood chemistry before breakfast, and we had believed that we could find the true state of affairs at that time. However, results obtained at that time furnished information as to the reactions of the organism to the diet. There, too, they gave these patients fixed amounts that were to be eliminated, such as water, salt, phthalein, urea and a quantitative diet for the test meal for renal function. The tests we gave were such that they demanded a certain fixed power of the kidney without taking into consideration the fact that there must be a different standard of function for the man engaged in heavy manual labor and for the one doing light work. It was a mistake to judge the functional capacity of the kidney of a longshoreman and an office clerk by the same standard. In the ambulant patient we had not only the opportunity to estimate renal function but also to determine whether the kidneys could properly meet the demands made upon them by the individual's habits—dietetic and otherwise.

The present way of rushing a patient to the hospital in order to test the renal function might give an idea of function from the pathologic physiologic point of view but not from the point of view of the demands made by the normal conditions of life. In making the tests upon ambulant patients they were now drawing the blood two hours or later after breakfast, and thus obtained the effect of food upon the patient. The test meal for renal function was carried out while the patient took his usual food except that he did not eat or drink after supper and carried out his routine duties. In other details the test did not differ from the usual routine procedure. Dr. Mosenthal gave a lantern slide demonstration bringing out the applicability of these tests to the ambulant patient. It was shown that by these means not only could the efficiency of the kidney (renal function) be estimated but also some idea of the individual's dietetic habits concerning especially the quality of water, salt, proteins and starches could be obtained. The main point emphasized was that blood chemistry and the two-hour renal test could be used as a measure of the adequacy of the patient's diet and the correctness of his mode of living and not as tests of renal function only.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF NEW JERSEY.

June, 1921.

ANATOMY.

1. Describe the endocardium.
2. Beneath what points on the anterior chest surface are the cardiac valves?
3. Give the origin and course of the pulmonary artery.
4. Give a general description of the cerebral veins.
5. Locate and describe the lacrimal gland.
6. Give the origin, course and distribution of the seventh nerve.
7. Name the flexor muscles of the forearm.
8. Name and locate the accessory sinuses of the face.
9. Locate and describe the cecum.
10. Locate and describe the bladder.

PHYSIOLOGY.

1. Trace a morsel of food in its transit through the whole extent of the alimentary canal, giving the organs through which it passes, naming the distinctive divisions of each with their secretions.
2. Give the number and regular order of eruption of the temporary teeth, stating the months of age when they normally appear.
3. Name the columns of the spinal cord and give the functions of the nerve fibres in each column.
4. Describe briefly the chemical mechanism of defense of the body against infecting organisms, *i. e.* the physiology of immunity.
5. Describe the nerve supply of the heart muscle, and give the complete cycle of circulation of the blood.
6. Describe the physiological processes by which the

blood system is relieved of effete material, and supplied with new material.

7. Name four ductless glands, and describe briefly the function of each.

8. Name three secretions and three excretions, and describe the source and function of each.

9. Of what kind of muscle tissue is the rectus femoris a type, and what is its function and nerve supply.

10. What physiological functions are affected in conditions causing (*a*) aphasia, (*b*) myopia, (*c*) muscular fatigue, (*d*) atrophy of a part, (*e*) inability to maintain equilibrium.

MATERIA MEDICA AND THERAPEUTICS.

1. Name two drugs that raise blood pressure and name three that relax or lower blood pressure. In what class of cases are they indicated? Write a prescription for same.

2. What is the definition for emmenagogue? Name three, give dosage, and write a prescription for same.

3. Name the official iodine preparations, medicinal properties, dose, and methods of employment.

4. What is the specific treatment for diphtheria? State briefly how the remedy is obtained, dose and how it is administered.

5. Write a prescription for a case of scarlet fever in a child three years old, uncomplicated.

6. Describe the action and uses of salvarsan, dosage. Name class of cases in which you would use it. If toxic results ensue what poison does it resemble and what antidote is indicated.

7. Name five official preparations of opium, dosage and name antidote for same.

8. Give Latin name for theobromine, give dosage and indicate in what class of cases you would use it and why.

9. What is the Latin name for camphor? Give action and uses. What effect does it have on blood pressure?

10. Eucalyptus, describe action and uses. Name dosage. In what form is it usually administered?

CHEMISTRY.

1. Mention the general physical and chemical properties of urine.

2. State the most common and convenient antidote for poisoning by mineral acids.

3. Give the general properties of alkaloids.

4. What is the chemical composition of the blood?

5. Give symptoms and treatment of alcoholic poisoning.

6. Give the general properties of organic compounds.

7. What antidote should be employed in a case of strychnine poisoning.

8. Name five poisonous vegetable alkaloids and antidotes for two of them.

9. What is hemoglobin? What is its function?

10. What are the requirements of good drinking water?

ANSWERS.

ANATOMY.

1. The *endocardium* is a thin translucent membrane, consisting of a lining of endothelial cells which rest upon a fibroelastic tissue. The endothelial cells are flattened and nucleated, and are of an irregular outline. The subendothelial tissue consists of a network of white fibrous and yellow elastic tissues. A few involuntary muscle fibers (non-striated) may also be present. The endocardium lines the inner surface of the heart; by its reduplications it assists in forming the valves of the heart; and it is continuous with the lining membrane of the large blood vessels.

2. The *aortic valve* is behind the third intercostal space close to the left side of the sternum. *Pulmonary valve* in front of the aortic, behind the junction of the third rib, on the left side, with the sternum. *Tricuspid valve*, behind the middle of the sternum, about the level of the fourth costal cartilage. *Mitral valve* behind the third intercostal space, about one inch to the left of the sternum.

3. The *pulmonary artery* arises from the conus arteriosus of the right ventricle of the heart; it extends obliquely upwards and backwards, and passes first in front of the ascending aorta and then to the left of it, as far as the under surface of the arch of the aorta where it divides into the right and left pulmonary arteries. The artery is contained within the pericardium.

4. The CEREBRAL VEINS are divided into two sets, the superficial and the deep. The SUPERFICIAL VEINS: The *superior*, ten to twelve on each side, consist of the anterior, middle, and posterior veins which run in the sulci, and, joining with branches from the mesial aspect of the brain, empty into the superior longitudinal sinus. The *inferior* consists of the middle cerebral vein, in the Sylvian fissure, which joins the cavernous sinus, and the great anastomotic vein, in the posterior branch of the same fissure, communicating with the middle meningeal veins and joining the superior petrosal sinus. The DEEP VEINS finally converge to two trunks, the *venæ Galeni*. These run backward in the velum interpositum, the right and left, lying side by side, and unite into the *vena magna Galeni*, which joins the straight sinus. Each vena Galeni is formed by the union of the *choroid* vein and the *vena corporis striati*, and is joined by the *basilar* and other small veins, while the vena magna receives tributaries from the occipital lobes of each side and from the upper surface of the cerebellum.—(From Little's *Anatomy.*)

5. The *lacrymal gland* occupies a depression in the supero-external angle of the orbit; the anterior margin is connected to the back part of the upper eyelid. The ducts (twelve or fourteen) open by apertures, placed in a row, at the inner surface of the upper lid. The *lacrymal canals* commence at the *puncta lacrymala*, which are the openings of the canaliculi, and, arching in the free edge of the lid, pass inward to open into the *lacrymal sac*. The *lacrymal sac* is placed in a groove formed by the lacrymal bone and the nasal process of the superior maxilla, and inferior turbinal bones, leads from the tensor tarsi; it is the dilated upper end of the nasal duct.—(*Aids to Anatomy.*)

6. FACIAL NERVE. It has its superficial origin in the superior end of the medulla, in the groove between the olivary and restiform bodies; its deep origin is from the floor of the fourth ventricle, anterior and external to the nucleus of the sixth nerve. It passes "forward and outward to enter the internal auditory meatus; it lies upon a groove on the auditory nerve, with the portio intermedia of Wrisberg between, and at the bottom of the meatus it enters the aqueductus Fallopii, along which it runs first outward between cochlea and vestibule as far as hiatus Fallopii; then backward in internal wall of tympanum, just above fenestra ovalis, at the turn presenting a swelling, the geniculate ganglion; and finally it passes downward, to emerge from the bone at the stylomastoid foramen; it then passes outward and forward in the parotid, dividing behind the ramus of the jaw into temporo-facial and cervico-facial branches, which further subdivide and intercommunicate, forming the pes anserinus."—(*Aids to Anatomy.*)

The facial nerve is distributed to the muscles of the face, scalp, external ear; also to platysma, buccinator, stylohyoid and posterior belly of digastric. It is the motor nerve to the muscles of expression. Through the chorda tympani it is a nerve of taste and a vasodilator of the vessels of the submaxillary and sublingual glands. The *pars intermedia* is a small bundle of nerve fibers lying between the facial and auditory nerves, and it is connected with both of these nerves. It is a sensory nerve; and is closely associated with the chorda tympani.

7. FLEXOR MUSCLES OF THE FOREARM. *Superficial group:* Pronator radii teres, flexor carpi ulnaris, flexor carpi radialis, palmaris longus, and flexor sublimis digitorum. *Deep group:* Flexor profundus digitorum, flexor longus pollicis, and pronator quadratus.

8. THE ACCESSORY SINUSES OF THE FACE, are: (1) *The frontal sinuses*, situated immediately above the root of the nose, between the two layers of the vertical portion of the frontal bone. (2) *The antrum of Highmore*, situated in the body of the superior maxillary bone; it is above the mouth, and below the orbit.

9. The *cecum* is a blind pouch which forms the commencement of the large intestine. It is situated in the right iliac fossa, immediately behind the abdominal wall, and above the outer half of Poupart's ligament.

It may lie on or to the right side of the psoas muscle, or in the pelvis; and is of very variable size. Its length may be from two to four inches, and its width about the same. It is generally covered by peritoneum, and is usually freely movable. Its shape is variable, and it is generally classified under one of four possible types. From the cecum is given off the vermiform appendix. The ileocecal valve opens into the large intestine at the point of junction of the cecum with the ascending colon.

10. The *urinary bladder* is a hollow musculo-membranous viscus, situated chiefly in the pelvic cavity, but when fully distended it extends into the abdominal cavity. It lies behind the pubes and the rectum in the male, and between the pubes and cervix uteri and upper part of the vagina in the female. On the inside, three openings are observed, the two ureteral openings behind and that of the urethra in front; the space between these openings is called the trigone. The peritoneum covers the superior surface of the bladder and extends for a variable distance over the anterior surface; that part of the anterior surface which is not covered by peritoneum is called the prevesical space of Retzius. Most of the posterior surface is covered by peritoneum.

The *attachments* are a number of ligaments, five true and five false ones; the true ones are two anterior or puboprostatic, from the back of the os pubis to the front of the neck of the bladder; two lateral, which are expansions of the pelvic fascia; and the urachus, extending between the summit of the bladder and the umbilicus. The false ligaments are peritoneal folds; two posterior, from the back of the bladder to the rectum in the male and the uterus in the female; two lateral, from the iliac fossæ to the sides of the bladder; and one superior, from the summit of the bladder to the umbilicus. In addition, the bladder is attached to the ureters, urethra, and rectum; also to the prostate in the male, and to uterus and vagina in the female.

The *arteries* are the superior, middle, and inferior vesical, and branches from the obturator and sciatic, all from the internal iliac; in the female, there are additional branches from the uterine and vaginal arteries. The *veins* form plexuses around the neck, base, and side of the bladder, and end in the internal iliac vein. The nerves are derived from the hypogastric plexus of the sympathetic, and from the third and fourth sacral nerves.

PHYSIOLOGY.

1. DIGESTION. (1) *In the mouth* the food is crushed, mixed with saliva, and reduced to a pulp; a certain amount of starch is converted into maltose and rendered slightly alkaline. Fats and proteids are unaltered. (2) *In the stomach*, the contents are rendered acid, conversion of starch into sugar ceases, connective tissue of fats is dissolved, and fats are set free. Proteids are disolved and proteoses and peptones formed. The albuminous foods are dissolved for the most part, and a grumous mixture of peptones, liquid fats, and starches is formed, which is termed chyme, and is gradually passed through the pylorus into the intestine. (3) In the *small intestine* the chyme is mixed with the bile and the pancreatic juice; the reactions become alkaline. Proteids are split up into proteoses and peptones, and these are further split into polypeptides and amino-acids; starches are converted into maltose; fats are emulsified and saponified; and the products of digestion are now ready for absorption.

The products of digestion find their way into the blood by two routes: (1) By the blood vessels of the gastrointestinal tract, which unite to form the portal vein; and (2) by the lymph vessels of the small intestine, which converge to empty into the thoracic duct. The water, inorganic salts, proteids and sugar go by way of the portal vein to the ascending vena cava; and the fats go by way of the thoracic duct to the junction of the left subclavian and internal jugular veins.

The process of digestion is carried on mainly by various enzymes:

DIGESTIVE SECRETION.	ENZYMES.	ACTION.
Saliva	Pytalin.	Changes starch into dextrin and sugar.
Gastric juice...	Pepsin.	Changes proteids into proteoses and peptones in an acid medium.
	A curdling ferment.	Curdles the casein of milk.
Pancreatic juice.	Trypsin.	Changes proteids into proteoses and peptones, and afterward decomposes them into polypeptides and amino-acids; in an alkaline medium.
	Amylopsin.	Converts starches into maltose.
	Steapsin.	Emulsifies and saponifies fats.
	A curdling ferment.	Curdles the casein of milk.

2. *The temporary teeth* are twenty in number, ten in each jaw. The order of their eruption is as follows: Central incisors, at about six months; lateral incisors, at about nine months; first molar, at about twelve months; canine, at about eighteen months; and second molar, at about twenty-four months.

3. *The columns of the spinal cord*, are the anterior, the lateral and the posterior columns on each side. *The anterior column* is divided into: (1) the direct pyramidal tract, whose fibers are efferent; and (2) the anterolateral ground bundle, whose fibers are efferent. *The lateral column* is divided into: (1) the anterolateral tract of Gowers, whost fibers are afferent; (2) the lateral limiting tract, some of whose fibers are afferent, and some efferent; (3) the crossed pyramidal tract, whose fibers are efferent; (4) the direct cerebellar tract, whose fibers are afferent. *The posterior column* is divided into: (1) the column of Burdach, whose fibers are afferent and associative in function; (2) the column of Goll, whose fibers are afferent; (3) Lissauer's tract, whose fibers are afferent.

4. The *chemical defenses of the body against infection*, are: The acidity of the gastric juice and of the urine; the bactericidal action of the blood and lymph; the action of the leucocytes and phogocytes; the alkalinity of the blood; the agglutinating action of the blood; the power of the blood to form antibodies.

5. The *nerve supply of the heart muscle* is threefold: (1) From the vagus nerve (inhibitory); (2) from the sympathetic system (accelerator); and (3) from the intrinsic cardiac ganglia. The cardiac center is in the medulla.

The *cycle of the circulation of the blood* is the course or circuit of the blood from the heart, through the body, and back to the heart. Beginning at the left ventricle of the heart, the blood flows through the left semilunar valve into the aorta, from which branches are distributed to every part of the body, through the capillaries to the veins, from the veins to the venæ cavæ, thence to the right auricle of the heart. From the right auricle, through the tricuspid valve to the right ventricle, thence through the right semilunar valve to the pulmonary artery to the lungs, from the capillaries in the lungs to the pulmonary veins, thence to the left auricle, and through the mitral valve to the left ventricle, to begin the circuit again.

6. The blood system is relieved of effete material, by: (1) The lungs; (2) the liver; (3) the kidneys; and (4) the skin. It is supplied with new material by: (1) the alimentary canal; (2) lungs; (3) skin; (4) lymphatics; (5) liver; and (6) spleen.

7. The *ductless* glands are: The spleen, thymus, thyroid, parathyroids, suprarenals, carotid, coccygeal, pituitary, and pineal glands.

The *function of the spleen:* The following theories have been held: (1) It is a source of production of the white blood corpuscles; (2) it is a source of production of the red blood corpuscles during fetal life; (3) it is a place where the red blod corpuscles are destroyed; (4) uric acid is produced in the spleen; (5) an enzyme is

produced in the spleen and is carried by the blood to the pancreas, where it converts the trypsinogen into trypsin.

The *function of the thyroid* is not definitely settled; (1) it has some trophic function, regulating oxidation in the body, and it is supposed to have also a special influence on the vasomotor nerves, the skin, the bones, and on the sexual functions; (2) it is supposed to antagonize toxic substances, and (3) it produces an internal secretion.

The *function of the thymus* is not settled; it is said: (1) To be a blood-forming organ; (2) to have influence on growth and nutrition; (3) in hibernating animals it is supposed to store up materials which can be utilized during the period of inactivity.

The *function of the suprarenals* is not definitely settled; they produce an internal secretion which is probably necessary to life; it is supposed that they are able to destroy or remove some toxic substance produced elsewhere in the body; muscle tone and blood pressure are increased.

8. THREE SECRETIONS: (1) *Milk*, secreted in the mammary glands; *function*, to nourish the infant. (2) *Saliva*, secreted in the salivary glands; functions, (1) To moisten the mouth, (2) to assist in the solution of the soluble portions of the food, and thus (3) to administer to the sense of taste, (4) to lubricate the bolus of food, and thus (5) to facilitate the acts of mastication and deglutition, and (6) to change starches into dextrin and sugar.

(3) *Gastric juice*, secreted in the stomach; functions, to change proteids into proteoses and peptones, and to curdle the casein of milk.

THREE EXCRETIONS: (1) Urine, excreted by the kidneys. (2) *Sweat*, excreted by the skin. (3) *Carbon dioxide and water*, excreted by the lungs.

9. The *rectus femoris* is a type of voluntary muscle tissue. Its *function* is to flex the hip joint. Its *nerve supply* is the anterior crural.

10. In *aphasia*, there is (1) loss of power of speech, and (2) inability to understand spoken or written language.

Myopia is near-sightedness; parallel rays of light are brought to a focus in front of the retina.

In *muscular fatigue*, the muscle loses its irritability.

Atrophy of a part may occur from disuse, from pressure, or from interference with its blood or nerve supply.

Inability to maintain equilibrium results from disturbance of the semicircular canals, and from disease of the cerebellum.

MATERIA MEDICA AND THERAPEUTICS.

1. *Two drugs that raise blood pressure:* Strychnine, epinephrin. *Indicated in:* Collapse, shock, hemorrhages.

Three drugs that lower blood pressure: Aconite, nitroglycerin, amyl nitrite. *Indicated in:* Eclampsia, angina pectoris, high arterial tension or in chronic nephritis, Raynaud's disease, erythromelalgia.

℞ Spiritus glyceryis nitratis 5j
Sig.: One or two drops in a teaspoonful of water q. 3 h.

2. *Emmenagogue* is an agent used to restore menstruation. *Three examples:* Manganese dioxide, gr. ij; Potassium permanganate, gr. jss; Extract of aloes, gr. j.

℞ Extracti aloes .....gr. 1
Ferri sulphatis exsiccati 5j
Asafœtidæ ..... 5ij Misce.
Fiant pilulæ No. 1
Signa.: Take one or two pills, three times a day.

3. The official preparations and doses of iodine and the iodides are: Iodine, 1/10 of a grain; compound solution of iodine, 3 minims; tincture of iodine, 1½ minims; potassium iodide, 7½ grains; sodium iodide, 7½ grains; ammonium iodide, 4 grains; strontium iodide, 7½ grains; zinc iodide, 1 grain; diluted, hydriodic acid, 15 minims; syrup of hydriodic acid, 1 dram.

"*Iodine* is alterant, rubefacient, vesicant caustic, antiseptic, and parasiticide. It is used locally in the form of the tincture in sprains and bruises, over the chest in various lung troubles, in lupus, in chronic rheumatism, in pleurodynia and intercostal neuralgia, in ringworm, and in erysipelas. It is administered internally in diseases associated with nutritional disorders, as tuberculosis in its various forms, in hypertrophy of the thyroid gland and tonsils, in cervical and ovarian cysts, and in the late stages of syphilis. It may be employed in inhalations. It is of value as a local application in rhinology, laryngology, and even in ophthalmology.

"The *iodides* are used to aid in the absorption of inflammatory products, as in pneumonia, pleurisy, etc., and in tertiary syphilis, chronic rheumatism, etc. In tonsillitis and sore throat they are used as a gargle (gr. 2/5 to 5i). The most generally used iodide is that of potassium, dose, gr. 5-5i in solution. Sodium iodide and strontium iodide are often used. Dose, gr. 5-5ss. Ammonium iodide is the most irritant and most energetic in action. Dose, gr. 2-10. Hydriodic acid in 1 per cent. solution is frequently employed in the form of syrup. Dose, 5i-4. The compound solution of iodine, or Lugol's solutions, is given internally in doses of ɱj-5, diluted.

"The tincture of iodine is used locally only. An ointment of iodine may be applied locally in certain inflammations."—(Gould and Pyle's *Pocket Cyclopedia.*)

4. *The specific treatment for diphtheria* is diphtheria antitoxin.

"Diphtheria antitoxin is obtained from the horse, the animal having been rendered artificially immune by repeated injections extending over a period of several months of gradually increasing quantities of the strongest diphtheria toxin. As the bacilli themselves are not injected, the horse does not become infected with diphtheria, but he gradually acquires a tolerance for the toxins of the disease and develops in his blood a substance (antitoxin) which has the power to neutralize those toxins. At the proper time, when it is thought that his blood has acquired the requisite degree of potency, the animal is bled, and the serum—the part of the blood containing the antitoxin—is carefully separated from the cloth, filtered, and standardized. The last procedure is accomplished by determining the quantity of antitoxin serum required to offset the effects of the minimum quantity of toxin necessary to kill a guinea-pig in a definite time. The strength of the antitoxin is measured in units, a unit containing the amount of antitoxin required to save the life of a guinea-pig which has been injected with 100 fatal doses of toxin."—(Stevens' *Materia Medica.*)

The antitoxin is injected into the loose subcutaneous tissue of the back, flank, or abdomen. The *immunizing dose* is from 500 to 15,000 units. The *curative dose* is from 5,000 to 20,000 units.

5. *In scarlet fever:*

℞ Potassii citratis 5j
Spiritus ætheris nitrosi.....3iv
Aquæ destillatæ ....q. s. and 5iij Misce.
Signa: One teaspoonful every two hours if the urine is highly colored.

6. *Salvarsan is indicated* in: "(*a*) Early cases of syphilis in which contagious manifestations are appearing in rapid succession, in spite of efficient mercurial medication. (*b*) Cases in which, for family or social reasons, it is of special importance to limit the production of infective material or cause the disappearance of symptoms in the shortest possible time. (*c*) Cases in which the symptoms are recalcitrant to the action of mercury, or in which, from idiosyncrasy, that drug cannot be exhibited in sufficient dose. (*d*) Cases of syphilophobia and syphilomania, whether showing symptoms or not; its psychic action in these instances being of greater importance than its therapeutic effect. (*e*) Very early cases of the sequelæ of the luetic infection, before organic changes have occurred."

Salvarsan is contraindicated in: "(*a*) Cases that are doing well, *i.e.* in which the disease is pursuing its normal mild course under ordinary medication. (*b*) Cases with serious organic lesions of the eyes, kidneys, heart, or other internal organs. (*c*) Cases with postsyphilitic or parasyphilitic disease of the internal organs, more especially of the nervous system."—(*Progressive Medicine.*)

The *action of salvarsan* is unsettled; it was at first believed that it combined with and destroyed the protoplasm of certain parasites found in the blood and tissues; it has also been taught that its action is of the nature of a complement-fixation reaction. Besides its

use in syphilis, it has been used in yaws, malaria, relapsing fever, trypanosomiasis, leprosy, anemia, filaria. Its *toxic results* resemble those of arsenic. There is no generally recognized antidote; intramine is said, by some, to be the antidote.

7. *Five official preparations of opium, with dosage:* Powdered opium, 1 grain; extract of opium, half a grain; powder of ipecac and opium, 7 grains; tincture of opium, 7 minims; camphorated tincture of opium, 2 drams.

Antidote, potassium permanganate.

8. The Latin name for theobromine is Theobromina. Dose is 5 grains. It is used in dropsy, as a diuretic, particularly in renal dropsy; it is non-irritating to the kidney.

9. The Latin name for camphor is Camphora.

Action: "It is a cutaneous stimulant and anesthetic; internally it is stomachic, carminative, antiseptic, and a cardiac, cerebral and medullary stimulant. Large doses cause delirium with hallucinations and epileptiform convulsions, which are followed by collapse. In fever it has some antipyretic action.

Uses: "Externally as a counterirritant and anodyne; internally in vomiting, flatulence, diarrhea, acute coryza, bronchitis, emphysema, socalled typhoid pneumonia, typhus and typhoid fever, the strangury caused by cantharides, nervousness and hysteria, nervous dysmenorrhea, after-pains, and delirium tremens; by suppository in cystitis, enlarged prostate, and other affections of the genitourinary organs; by enema for thread-worms. It is an excellent remedy for the night sweats of chronic tuberculosis."—(Wilcox's *Materia Medica.*)

Camphor increases the blood pressure.

10. EUCALYPTUS. *Action:* "Antiseptic; disinfectant; rubefacient; stomachic; carminative; large doses cause severe gastrointestinal irritation. By small doses the heart's action is stimulated and a rise in blood pressure is produced, but large doses depress the heart and cause a fall of blood pressure, with great muscular weakness and lowered temperature. It restricts the movements of the white blood corpuscles. Stimulation of the central nervous system is only very transient, and is followed by marked depression. Toxic doses paralyze the respiratory center in the medulla. Eucalyptus has been thought by some to have slight antiperiodic properties and also cause contraction of the spleen to a limited extent. It is somewhat irritant at the points of elimination, and therefore has more or less action as a diaphoretic, expectorant and diuretic, and as a stimulant to the genitourinary tract."

Uses: "Locally, wounds; indolent or unhealthy ulcers; as a counterirritant in affections of the chest and of the joints; diphtheria; pharyngitis; tonsillitis; cancer of the rectum or uterus; bromidrosis; alopecia; chronic eczema. By inhalation, ozena; diphtheria; bronchitis with fetid expectoration; phthisis; gangrene of the lungs. Internally, atonic dyspepsia; chronic gastric and intestinal catarrh; vomiting and indigestion caused by sarcinæ; convalescence from acute diseases; hysteria; neurasthenia; headaches; cerebral anemia; subacute and chronic catarrhal affections of the bronchial mucous membrane and that of the genitourinary tract; malarial poisoning and cachectic conditions generally."—(Wilcox's *Materia Medica.*)

It is usually administered in the form of the oil of eucalyptus.

CHEMISTRY.

1. *Normal urine* is a yellowish fluid secreted by the kidneys to the amount of about 1,200-1,500 c.c. daily; specific gravity, about 1.015 to 1.025; acid reaction (due to acid sodium phosphate); it has a characteristic odor and a salty taste. Its normal constituents are: Water, urea, uric acid, urates, hippuric acid, kreatin, kreatinin, xanthin, hypoxanthin; sulphates, chlorides, and phosphates of sodium and potassium; phosphates of magnesium and calcium; nitrogen, and carbon dioxide.

2. For *poisoning by mineral acids*, a convenient antidote is magnesia (magnesia usta) in a small quantity of water.

3. *Alkaloids* are nitrogenous, basic substances, of alkaline reaction, and capable of uniting with acids to form salts in the same way that ammonia does. Most alkaloids are solid, crystalline, contain carbon, hydrogen, nitrogen, and oxygen, are sparingly soluble in water, but are soluble in alcohol, their salts are freely soluble in water, they are generally bitter in taste. A few alkaloids are liquid.

4. BLOOD. *Composition:* Plasma and corpuscles. The *plasma* consists of water, solids (proteids, carbohydrates, fat extractives, and inorganic salts), and gases in solution (oxygen, carbon dioxide, and nitrogen). The *red corpuscles* consist of water and solids (hemoglobin, proteids, fat, and inorganic salts). The *white corpuscles* consist of water and solids (proteid, leuconuclein, lecithin, histon, etc.).

5. ALCOHOLIC POISONING. *Symptoms:* "The symptoms presented will depend upon the amount, character, and rapidity of the dose, together with the susceptibility of the individual. They will vary from the ordinary symptoms of drunkenness to those of acute narcotic poisoning, the most common being irritation of the gastro-intestinal tract, muscular incoördination, weakness, and hallucinations; the temperature is as a rule lowered, unconsciousness and coma follow. If a large quantity of concentrated alcohol is taken and the stomach is not relieved by vomiting, collapse and death may follow. The pupils are as a rule dilated, the conjunctivæ congested, respiration stertorous, and there may be a considerable amount of lividity. Convulsions may sometimes appear, and death may follow either from paralysis of respiration or from overstimulation of the heart. Death may occur within one-half hour after the taking of the toxic dose. In some instances a considerable amount of froth may appear upon the lips.

Treatment: "The stomach should be emptied of its contents; strychnine, ammonia, or other stimulant administered. Black coffee is sometimes indicated; fresh air, artificial respiration, and electricity."—(Dwight's *Toxicology.*)

6. *General properties of organic compounds:* They may be solids, liquids, or gases; if solid, may be crystalline or amorphous; they may be volatile or non-volatile, and they are very liable to undergo change when acted upon by heat or reagents. The more complex they are the more readily they undergo change.

7. The *chemical antidote to strychnine* is solution of potassium permanganate.

8. *Five poisonous vegetable alkaloids:* Aconitine, atropine, strychnine, nicotine, morphine.

Antidote for morphine, solution of potassium permanganate.

Antidote for most alkaloids, solution of tannin.

9. *Hemoglobin* is the coloring matter of the blood: it is found in the red corpuscles, and is composed of carbon, hydrogen, oxygen, nitrogen, sulphur and iron; it carries the oxygen from the lungs to the tissues of the body. When pure, it is a crystalline solid, red or purple in color, more or less soluble in water; it dialyzes very slowly.

10. *Characteristics of a good drinking water:* (1) It should be clear and limpid. Cloudy and muddy waters should be avoided. (2) It should be colorless. A greenish or yellowish color is usually due to vegetable or animal matter in solution or to organisms. (3) It should be odorless; especially free from sulphuretted hydrogen or putrefactive animal matter. (4) It should not be too cold, but should have a temperature of from 46° F. to 60° F. (5) It should have an agreeable taste; neither flat, salty, nor sweetish. A certain amount of hardness and dissolved gases give a sparkling taste. It should contain from 25 to 50 c.c. of gases per liter, of which 8 to 10 per cent. is carbon dioxide and the rest oxygen and nitrogen. (6) It should be as free as possible from dissolved organic matter, especially of animal origin. (7) It should not contain too great an amount of hardness. A certain quantity of saline matter is necessary, however, to give it a good taste. It should not contain over three or four parts of chlorine in 100,000 parts of water.—(From Bartley's *Chemistry.*)

(*To be continued.*)

Combination of Cancer and Tuberculosis of the Colon.—Hartmann and Renaud removed a tumor of the cecum found to consist of epitheliomatous and tuberculous tissue intimately associated. The neoplastic seems to have developed in the tuberculous tissue.—*La Presse Médicale.*

Medical History.

NEW AND OLD BOOKS.

XVII. THE HISTORY OF ST. BARTHOLOMEW'S HOSPITAL.

By JOHN RUHRÄH, M.D.,
BALTIMORE, MD.

THE thirty years' labor of Norman Moore on the history of St. Bartholomew's Hospital finally resulted in two large, beautifully printed volumes of some fifteen hundred pages, illustrated with a large number of copies of the charters and some views, not to overlook a beautiful reproduction of a photograph of the tomb of Rahere, the founder. Very fortunately the volume has as a frontispiece the portrait of the author, placed there at the request of Lord Sandhurst, the treasurer of the hospital, and it is very gratifying to the many readers of the works of Norman Moore that this has been done. It is a reproduction by Emery Walker of a portrait by Richard Grenville Eves.

It would not be possible in the short space allotted me to do justice to this wonderful piece of historical research. It is a record based on a very careful study of the many documents that have been preserved either at the hospital itself, or elsewhere, and for the term of years mentioned above these have been an object of loving study by the author. How well he has done his work will readily be appreciated by those who have been fortunate enough to have read any of the other writings on similar topics by the genial historian, whose life has been so largely associated with "Barts." Some of the material is taken from the cartulary of John Cok, and a large number of charters from this work, as well as others have been reproduced in part or completely.

When Rahere founded the hospital in the time of King Henry I, London was surrounded by a wall and Smithfield was a suburb to the eastward. Here were fields and forest lands and swampy ground, and here on Fridays was held a horse fair. Rahere was of lowly origin, but had managed to worm his way into the houses of the nobles and princes, but becoming convinced of the error of his ways, he determined to go to Rome, which he did. There he fell ill, and fearing death, vowed that if he were allowed to return to his own country he would build a hospital for the poor. He recovered and on his way home he had a vision that a four-footed, winged beast carried him to a high place. A stately figure appeared to him and said, "I am Bartholomew, the apostle of Jesus Christ. I am come to help thee in difficulties and to show thee the hidden things of heavenly mystery. Know that by will and command of the Trinity on high, I have chosen a place in the suburb of London at Smithfield where, in my name, thou shalt found a church and it shall be there a house of God, a tabernacle to the Lamb, a temple of the Holy Ghost."

After the building was started a great many cures were obtained, some of which are recorded. For example, a woman with a swollen tongue came to Rahere who had a relic of the true cross. He prayed for her recovery and then washed her tongue in water in which he had dipped the relic, and made the sign of the cross with it on her tongue, and she recovered. An interesting occurrence which one fears might shock the inhabitants of this land of ours is one in which it is recorded that Edena, wife of Edred, in the parish of St. Giles, was brewing and had only seven loads of malt and feared that less would prevent her beer coming off. However, she gave one to the men of St. Bartholomew's and then found she yet had seven, so counted them again and there were eight, and again, and there were nine, and the fourth time, and there were ten. She sent off the superabundance to the church. "The History of St. Bartholomew's" is filled with marvellous cures and miracles, many of which Moore has recounted. Rahere was succeeded by Thomas of St. Osyth's and to him the institution owed much, as Moore states that, "By his regulation of the relations of the hospital and the priory he gave to the former that independence which enabled it to weather the storm of dispossession which raged in the reign of King Henry VIII."

Another benefactor of the hospital was Henry Fitz-Ailwin, the first Mayor of London, and he is mentioned among the many who made grants to the institution. Moore devotes a long chapter to the state of St. Bartholomew's Hospital during the time of Fitz-Ailwin, and at the end pays a fine tribute to the early benefactors.

I cannot pass without mention of Alexander of Smithfield, one of the thirteenth century scribes who did so much to preserve the records of the time and whose fine vellums with their unfading ink and beautiful handwriting are still preserved. Moore has had reproduced some of the charters written by Alexander and they are beautiful examples of the vertical script of the period. The writing is in regular lines and the words spaced very much as in the printing of the present day.

In the reign of King Edward III, Thomas Sutton built his addition to the hospital, and the bells which called the brethren to prayers or to meals have, as Norman Moore points out, been commemorated in an immortal passage of literature: "And just as the last bell struck, a peculiar sweet smile shone over his face, and he lifted up his head a little, and quickly said 'Adsum,' and fell back. It was the word we used at school when names were called, and, lo, he whose heart was as that of a little child, had answered to his name, and stood in the presence of the Master." And so passed Colonel Newcome.

In the reign of King Richard II, one very notable piece of history is connected with the hospital, and that is that Wat Tyler, whose revolution took place at that time, fell from his horse and was carried to the hospital.

Among the notables connected with the history of the hospital is John Mirfeld, a well-read and industrious physician who will long be remembered as the author of the Breviarum Bartholomei. Brother John Cok, who wrote the cartulary of the hospital, also spent the greater part of his life within the walls and it is to his industry and forethought that future generations have a knowledge of the hospital during the Middle Ages. His portrait comes down to us in the cartulary, being woven in one of the illuminated initials. The page showing this has been reproduced as the frontispiece of the second volume of the history.

In the chapter about the Mediæval Property belonging to the hospital, Moore gives us many little views of various places and quotes a number of interesting lines from various authors relating to Duck Lane, in which some of the property of the hospital was situated and in which Norman Moore lived for twenty-one years. With the banishment of the religious orders from their ancient homes, the old order of the hospital came to an end. To quote Moore on this subject:

The good they did was put an end to, but the spoliations of the king, great as they were, could not extinguish benevolence in the land; and, though many men would no longer pray for the faithful departed, they still saw a duty in the care of the sick and the poor. St. Bartholomew's Hospital was one of the few places where the injured tree of charity began to put forth new branches, and soon flourished again.

King Henry VIII was petitioned that St. Bartholomew's and some of the other hospitals be placed under the order and governance of the Mayor of London and his brethren. The first petition is:

For the ayde and comforte of the poore, sykke, blynde, aged and impotent persones beyng not hable to helpe theymselffs nor havyng any place certeyn wheryn they may be lodged, cherysshed, and refreshed tyll they be cured and holpen of theyre dyseases and syknesse.

Since the charter of King Henry VIII, the receipts and the expenditures of the hospital have been recorded in a long series of ledgers of which the author of the history has made a remarkable account. At one time he notes that the ale consumed in a month cost the hospital 3 pounds, 12s., and the bread 53s. 6d. Much information also has been gleaned from a book called the Repertory in which the debts, leases, obligations, and so on, have been entered. Still other historical records are the journals of the meetings of the governors. I cannot do more than mention these, but on the day in which I write this, the House of Representatives has voted against the use of medicinal beer, so that one entry of a few lines may be quoted:

That the Cellar for stronge beare in this hospitall shalbe shut upp every Sabboth-day untill fiue of the clock in the afternoon, and then not to continue open longer than one hower, and alsoe that dureing that hower noe person or persons bee suffered to drinke therein but only to fetch what beare or ale they shall want into their severall wards.

We also read that on January 17, 1701, Sir Godfrey Kneller was admitted a governor, which recalls the fact that Sir Godfrey was a great friend of the famous Dr. John Radcliffe, who when he died left 500 pounds a year forever to St. Bartholomew's "for mending the diet of the patients." These names recall an incident not recorded by Moore. Kneller and Radcliffe lived in Bloomsbury and their gardens joined. For the convienence of both a door was cut in the wall, and Kneller, being annoyed by Dr. Radcliffe's servants breaking off his fine roses, wrote to the doctor and said that if he did not stop this he would be forced to nail up the door, whereupon Dr. Radcliffe replied that Sir Godfrey could do what he wished with the door as long as he did not paint upon it, to which the artist replied that he held Dr. Radcliffe in such high esteem that he would take anything off of him except his pills.

Dr. John Freind was admitted governor in 1722. He was the celebrated author of "The History of Physick from the Time of Galen to the Beginning of the Sixteenth Century."

Dr. John Caius has a chapter all his own, as he had much to do with the life of the hospital. He was born in 1510, and after being admitted a fellow of the College of Physicians, soon after came to live within the hospital and was a tenant there until his death. His benefactions to Cambridge and his publication, "A Boke of Counseill against the disease commonly called the sweate or sweatying Sicknesse," have kept his memory green.

I wish that space permitted me to mention more of these old worthies connected with the hospital. The most famous of all, of course, is William Harvey, to whom Moore devotes a long chapter. Of his successors I must mention the name of William Pitcairn who received from Dr. Askew the famous gold headed cane preserved at the Royal College of Physicians. Another chapter is devoted to the surgeons of the old guild and contains much interesting biographical material; and still another section is devoted to the corporation of surgeons, while the history of the teaching of medicine at St. Bartholomew's is outlined in the chapter devoted to that great teacher, John Abernethy. The apothecaries have not been forgotten, and part of the book tells of them. The remainder of the volume is given up to a consideration of the nurses, administrators, the medical school, present buildings, and the patients. In this last chapter there are a large number of fine incidents outlined in Norman Moore's inimitable style.

The volume closes as follows: "Such has been the history of St. Bartholomew's Hospital during eight centuries. Surely everyone who reads it will join in the wish always expressed at the feasts in the Great Hall:

"Prosperity to St. Bartholomew's Hospital, and Health and Ease to the Poor Patients."

Two Discourses by Samuel Bard on Medical Education in Early New York.—The Columbia University Press has recently published a reproduction in fac simile of two discourses dealing with medical education in early New York by Samuel Bard, professor in the Practice of Medicine in King's College and later president of the College of Physicians and Surgeons. In his introduction to the book Dr. Nicholas Murray Butler points out that at this time when Columbia University is undertaking a long step forward in the better organization of medical education and research it is important that there should be reprinted for the benefit of this generation the prophetic "Discourse Upon the Duties of a Physician; with some Sentiments upon the Usefulness and Necessity of a Public Hospital," delivered before the president and governors of Kings College at the commencement held on May 16, 1769, and also the "Discourse on Medical Education" delivered at the commencement at the College of Physicians and Surgeons on April 6, 1819, when Dr. Bard was president of the college. Dr. Bard lived to be seventy-nine years of age and died on May 25, 1921. Dr. Bard served not only as Professor of the Theory and Practice of Medicine,

but later as Professor of Chemistry, of Natural Philosophy and of Astronomy, and was considered an ornament to the profession wherever he served. Though time has wrought many changes and the science of medicine made much progress since Professor Bard defined the ideals and duties of the physician, his advice is as timely to-day as it was one hundred and fifty years ago. He says, "And be not alarmed, if I set out with telling you that your labors must have no end. No less than life and its greatest blessing, health, are to be the objects of your attention; would you acquit yourselves to your own consciences, you must spend your days in arduous inquiries, after the means of rendering those of others long and happy. Do not imagine, therefore, that from this time your studies are to cease; so far from it you are to be considered as just entering upon them; and unless your whole lives are one continued series of application and improvement, you will fall short of your duty." "You are," he says, "accountable for the errors of ignorance, unless you have embraced every opportunity of embracing knowledge." Professor Bard gives interesting advice as to the relative merits of ancient and modern medical writers and lays down rules for the guidance of the physician in his dealings with his fellow practitioner and his patients. At the present time when so many of the developments of modern medicine tend to smother the human element Professor Bard's advice is peculiarly fitting: "In your behavior to the sick, remember always that your patient is the object of the tenderest affection, to some one, or perhaps to many about him; it is, therefore, not only your duty to endeavor to preserve his life, but to avoid wounding the sensibility of a tender parent, a distressed wife, or an affectionate child. Let your carriage be humane and attentive, be interested in his welfare, etc." Professor Bard scores the slovinless of shotgun prescriptions and declares that it is impossible to learn the true virtue of medicines from compound prescriptions. The importance of autopsies as a means of improving knowledge and making further and useful discoveries in the healing art are set forth and the establishment of public hospitals, both as a means of furnishing medical care for the poor and as a teaching institution is urged.

In the discourse on medical education we find the question as to the value of classical learning discussed in truly modern fashion and the conclusion reached that "classical learning may justly be considered, and has been proved by long experience, to be the best preparation for any employment above those of the mechanical arts." The great error of the system of education of that day, according to Professor Bard, was that they were too much in a hurry and that young men began the practice of their professions at a period so early and after a preparation so slight that very few had acquired the prudence or the knowledge requisite to govern their conduct. He says "Could we keep our youth at school until sixteen, at college until twenty, in the counting house or at the study of the professions, until twenty-four or twenty-five years of age, they would be more generally useful in life." We learn, too, that the disparity between the compensation of the practitioner and an expensive medical education was a source of disquietude in those days as it is to-day. Professor Bard further insists that the practice of medicine can only be properly taught in a public hospital and dwells on the advantages of the laboratory, the dissecting room and the botannical garden over those of mere didactic teaching. Great progress has been made toward the realization of Dr. Bard's ideas of teaching medicine. From the material side the future bids fair to exceed his rosiest dream. In the pride of our material advantages and scientific advances it is, indeed, befitting to keep steadily in view the professional ideals he so ably inculcated.

Laennec.—The *Bulletin Medical* for August 24-27, 1921, xxxv 35, is devoted entirely to the memory of Laennec, whose death occurred about a century ago. For the past year the French medical journals have abounded in references to the activities and accomplishments of the deceased and it is clear that the world has never appreciated the genius and greatness of one whom they know of chiefly as the inventor of the stethoscope. Without the least bias toward hero worship one must admit that Laennec seems to have been not only a good example of a so-called universal genius, but that he was also in all respects a great man. Aside from his medical career he, who began life speaking two tongues, French and the Celtic Breton, became a polyglot, and as a child wrote poetry in both his mother tongues. He was a remarkable musician as well. He had all the precocity of genius, while his greatness of character is shown by the unfailing test that all he accomplished in his short life was the work of a confirmed invalid. He made his way in a worldly sense, beginning in poverty and rising in a short time to a state of financial prosperity. He succumbed only to incurable disease.

As to his medical career he was accomplished in nearly all of its possibilities. He was a born journalist and controversialist and at the age of 25 owned and edited a periodical. He made several discoveries in anatomy. Nominally a physician he was accomplished as an operating surgeon. As a medical diagnostician his skill was uncanny. Only the accident of being born ahead of the microscope prevented him from being a Virchow. His recognition of peritonitis and cirrhosis of the liver were samples of his pathological work. His epoch-making work in intrathoracic diagnosis was the fruit of his pathological knowledge as much as of his invention of the stethoscope. His most magisteral work, on pulmonary tuberculosis, paved the way for our present developments and he is said to have anticipated the greater portion of our modern lore on that disease. That his reputation was not much greater in the decades which followed his death, was due very largely to the fact that much of his best work was never published, although largely preserved in manuscript notes.

We know of no better way to aid in the rehabilitation of the former French prestige than the publication of an English translation of Rouxeau's recently completed life of Laennec for English and American readers.

MENSTRUAL DISTURBANCE AND PAIN IN TUBAL PREGNANCY.*

BY LEROY BROUN, M. D.,

NEW YORK,

ATTENDING SURGEON TO THE WOMAN'S HOSPITAL.

FOR the purpose of clearly understanding the cause of the hemorrhage in tubal pregnancy, let me make a comparison between the commencement of pregnancy in the uterus and in the tube.

Within a few hours after the entrance of the impregnated ovum in the uterus, the villi of the chorionic sac surrounding the ovum begin to burrow into the mucous lining of the uterine cavity in their search for nourishment and a resting place. Under the influence of the presence of the impregnated ovum, the uterine mucosa has become thickened and spongy, and within a few days the ovum is covered by a continuation of this thickened spongy mucosa, completely surrounding the impregnated ovum with its chorionic sac and villi.

When the impregnated ovum fails to reach the uterus and finds a resting place in the tube, a similar process takes place, yet under very different circumstances; in fact, these circumstances become pathological. There is no thickened spongy decidua or at least only an excuse for one. The chorionic villi in their erosive action, searching for nourishment, having no thickened spongy mucosa into which to imbed themselves, as in the uterus, rapidly make their way through the mucosa of the tube and become imbedded in its muscular wall.

Under the influence of pregnancy, the blood vessels of the uterus and of the tube become enormously dilated in the neighborhood of the implanted ovum. In the uterus the spongy thickened mucosa (decidua) is a protection against the erosive action of the villi; only the smaller capillaries are reached from which the villi obtain their nourishment.

In the tube, the spongy layer being absent, the villi eroding their way into the muscular wall itself, literally riddle it and perforate the larger blood vessels. The resulting hemorrhage is greater than can be taken care of, the escaped blood crowds the villi together, enters the capsularis, over-distends and ruptures it, and escapes through the open fimbriated end of the tube. If this escape is sufficient to relieve the pressure of the steadily forming clot in the intervillous spaces around the chorion, the thickened muscular wall of the tube, though weakened by the invasion of the villi, does not give way; the capsularis, however, becomes separated from its base of nourishment by the intervening clots and death of the impregnated ovum results.

If, however, the leakage through the open mouth of the tube is not sufficient to relieve the pressure above, a rupture of the riddled tubal wall must take place with a resulting hemorrhage of greater or less profuseness, depending on the size of blood vessels involved.

In nature's economy under the influence of pregnancy, whether in the tube or uterus, the lining membrane of the uterus becomes thickened and spongy. This decidual membrane in instances of tubal pregnancy differs from that of uterine pregnancy in having a more abundant blood supply on its surface, and in the spongy layer being not so well developed.

After the death of the fetus in the tube, uterine bleeding from the thickened uterine mucosa (decidua) becomes evident, and in the large majority of cases gives the patient the first symptom that something is wrong, causing her to seek the advice of her physician. In the majority of cases the uterine bleeding is simply a slight continued show extending over days or weeks; in others it amounts to a distinct hemorrhage and impresses the physician that a miscarriage has taken place, and frequently a curettage follows, especially if the patient shows the physician parts of the thickened decidua, similating the secundines of an abortion.

The appearance of uterine bleeding in the presence of tubal pregnancy does not at all times follow the classical course described in many texts, and which is usually prominent in the mind of the general practitioner. I refer to the classical description of the patient failing to menstruate at the expected time and later having irregular and recurring bleeding.

An examination of the history of fifty-five consecutive patients, who were operated on at the Woman's Hospital for tubal pregnancy, brings out the fact that sixteen followed the above classical course of having missed a period and later having irregular bleeding; 17 patients commenced the irregular uterine flow at the time of the expected normal period, and 16 others continued with an irregular flow within a few days after the occurrence of the normal period. In other words, two-thirds of the number did not follow the classical course of missing a period, suggestive of pregnancy.

Farrar, in her excellent paper on tubal pregnancy, brings out the same fact: in 100 consecutive cases she found that only 34 followed the course ordinarily accepted, of missing a period be-

*Presented to the West End Medical Society of New York City, May 28, 1921.

fore the onset of the flow; 30 dated the irregular flowing from the time of the expected period, and 35 commenced irregular bleeding after the cessation of a normal flow.

In the majority of cases the death of the impregnated ovum takes place within a few weeks after its implantation in the tube, on account of the hemorrhagic infiltration of the intervillous spaces by the increasing blood clot from the eroded blood vessels of the tubal musculature. The excess of blood finds its way through the open end of the tube and gradually forms a hematoma in the pelvis, which is plastered over by intestinal adhesions. Coincident with, or shortly after the fetal death, uterine bleeding from its richly supplied decidual vessels begins to take place. This is fortunately the pathological history of the largest number of cases.

In other instances, and these are in the minority, the erosive action of the villi has been sufficient to perforate the tube and the first evidence the patient has is an intensely severe lancinating pain, often attended by collapse. This may occur after an overdue period, or, as shown, without having missed a period or without any warning by previous uterine hemorrhage. The immediate danger of such an occurrence depends on the size of the enlarged tubal vessels that have been perforated. In some instances the hemorrhage is sufficient to cause death.

This brings us to the subject of pain in tubal pregnancy with its escape of blood into the cul-de-sac or in the general peritoneal cavity. Recently there was placed under my care by Dr. J. Gardner Smith, a patient upon whom he had made a diagnosis of tubal pregnancy, with an hematocele rupture in the cul-de-sac. Upon her entrance into the hospital Dr. Smith's diagnosis was confirmed and the patient was kept in bed for observation on account of her temperature being almost 103° and the differential blood count being considerably higher than that usually associated with extra-uterine pregnancy. The possibility of a superimposed colon infection of the blood clot was the reason for this precaution.

During the three days the patient was being studied, she had practically no pain, excepting a vague tenderness in the pelvis. I was called to her on the evening of the third day on account of severe abdominal pain, which required almost three-fourths of a grain of morphine before even a slight cessation of the pain was noticeable. She was operated on at once. The findings were about an ounce of free clotted blood among the intestines and a large hematocele in the cul-de-sac, which was walled off by intestinal adhesions. There was no colon infection and an even recovery followed. The severity of the pain of this patient was most impressive and one that the surgeon rarely has the opportunity of seeing, the physician in attendance having usually controlled it before he arrives.

The desire to know the frequency of such occurrences and the condition under which they occurred was the reason of the search of the histories from which this paper is the result. Ninety-nine consecutive histories were examined: of these forty-four were of private patients, and they were not utilized in the present study.

Among the remaining fifty-five, twenty-two gave a history of sharp, severe pain, which recurred at intervals and lasted for a varying time at each recurrence. Cases of this class have as the cause of the recurring intense pain in abdomen, the escape of *free blood* into the general peritoneal cavity and not the presence of encapsulated blood in the cul-de-sac. As examples of this

Hospital No. 21,129 had an abortive flow of one day on June 30, and commenced to flow irregularly July 16, with a severe four days' abdominal pain and backache. *Findings*—Large quantity of free blood in the general cavity; tube ruptured; fetus in cul-de-sac with much clotted blood.

Hospital No. 19,117 had a delayed period; two weeks later severe pain in the right lower quadrant attended by uterine bleeding; decidua expelled one week later. *Findings*—Free clotted blood in peritoneal cavity with clots in cul-de-sac; right tube involved.

Hospital No. 20,216 had a delayed period; has been flowing since January 25, and entered hospital a month later. Pain sudden and of much severity, causing marked shock. *Findings*—Abundant free blood in general cavity, also in cul-de-sac.

Hospital No. 18,152 had a delayed menstruation, severe abdominal pain for two hours which followed sexual intercourse; two other attacks of like severity at intervals of two and four days. *Findings*—Abdominal cavity full of blood, fresh and clotted; right tube ruptured.

The remaining cases in this series are a repetition in a varying degree of the above histories cited. In every instance of sudden severe pain, the finding at the operation was *free clotted blood* in the general cavity in addition to the encapsulated clots in the pelvis.

In another class are twenty who stated that the pain was chiefly pelvic and varied greatly in character; with some of these patients the pain was slight, amounting to little more than a constant pelvic discomfort; in the majority the discomfort was more marked, yet was confined to the pelvis and constant in character, being more marked when in the upright position.

In this class of cases, which are practically as frequent as those having sudden severe pain, the distress as noted is not so striking and in many instances would even pass unnoticed by the patient, except for the continued flow, which causes them to seek advice. As examples of such instances we note:

Hospital No. 17,784 had bleeding since the period of January 1, 1917; admitted to hospital January 14, 1917. The patient complained of no pain. *Findings*—Ruptured ectopic, small amount of encapsulated blood in pelvis.

Hospital No. 19,053 began to bleed shortly after regular period of January 21, 1917; this continued until admission to the hospital, a month and a half later. The patient complained only of slight abdominal cramps at the beginning of flow; none during the flow. *Findings*—Right ruptured tube with encapsulated pelvic clots. Again

Hospital No. 18,173 has been flowing since March 5, 1917. Soreness, but not marked pain. *Findings*—Small amount of blood in right tube, encapsulated blood in pelvis.

Hospital No. 18,529 has been flowing since last period on April 10. Entered hospital May 17. No pain. *Findings*—Small amount of blood in cul-de-sac.

The pain is not, however, uniformly so mild as in the above cases, as for example:

Hospital No. 18,431 had bleeding one month; pain intermittent, with steady backache. *Findings*—encapsulated pelvic blood.

Hospital No. 18,323, bleeding two months, with dragging as if the pelvis floor was giving way. *Findings*—Much clotted blood in pelvis.

Hospital No. 19,358, bleeding since September 3, the last period being in June. The pain is severe and sharp. *Findings*—Large organized clot in pelvis.

It will be seen that the pain, in instances of escaped blood encapsulated in the pelvis, is not of the same character and severity as in the escape of free blood in the peritoneal cavity. The pain is not only of a different character, but varies greatly in degree, from instances of mild discomfort to that of much pelvic distress. Apparently this depends on the amount of blood effused in the encapsulated area.

It is in the less typical cases of absence of or slight pain that the diagnosis is most apt to be overlooked. The continued abnormal flow, however, should attract our attention to the possible conditions present and cause a careful pelvic examination.

Another class includes seven, who were operated on before any rupture or escape of blood had occurred, the only pain symptom in these instances was that of discomfort on the side involved. A striking illustration of the lack of severe pain in the absence of escaped blood was in a case of abdominal pregnancy:

Hospital No. 20,942. This patient missed her period in April, 1917; felt life in November, 1917; began to menstruate in February, 1918, from which time her abdomen began to grow smaller, until the time of her admission to the hospital in June, 1918. An unruptured sac, 20 cm. in diameter, containing a mummified fetus was found. There was no mention of pain in her history.

The other extreme of size is in Hospital No. 17,147. The last period was on October 4, 1916. Continuing to bleed and having had a former operation for tubal pregnancy of the left side, she sought advice, and entered the hospital October 13. The pain in the right side was only a slight discomfort. The finding at the operation was a tubal pregnancy in the middle third of the tube of 2 cm. diameter.

In the remaining unruptured cases, the recognition of the condition present was made by the persistence of bleeding after a regular period, associated with which was a slight pain or recurring cramps on one side, when no discomfort of this character had been noted before.

In one instance, Hospital No. 18,068, a double ectopic, the rupture was almost complete. Here the pain was greatest. This patient had been curetted for a supposed miscarriage. The flowing continued, as also the pain. The finding at operation was a clot protruding from the open end of the right tube, and from the center of the left tube an unruptured ectopic sac was showing through the peritoneal covering.

The remaining four of the histories examined do not fall under any of the above three classes. They were chiefly instances of the almost constant symptomatic uterine flow with discomfort of varying degree on one side. The findings were encapsulated tubal hematocele, with closed fimbriated extremity of the tubes. In one the pain complained of by the patient was located by her under the liver. The operative finding showed right tubal pregnancy.

Farrar, in her excellent paper covering the examination of 186 cases of ectopic pregnancy at the Woman's Hospital, to which I have already referred, states, after an exhaustive tabulation study of the character and location of the pain, that "in only 18.8 per cent. of the cases was the pain of the character ordinarily considered peculiar to ectopic gestation. In the remaining cases it was not to be differentiated from that of any severe pelvic lesion."

In my own experience, and from the study of the cases on which this paper is based, it would have been nearer correct if she had omitted the word "severe," since, as shown, a certain percentage of the cases have very slight pain and in rare instances none. Such instances occur in early unruptured tubal gestation and in cases where the fetus has probably died early, giving only a slight distention of the tube and only a small amount of encapsulated blood around the open end of the tube.

The possibility of such an absence of pain or that of a mild discomfort should always be borne in mind to avoid overlooking the true condition and possibly subjecting the patient to a sudden rupture that might be most disastrous. When such a condition exists in the presence of a delayed menstruation followed by a continued show or an unusual continued show independent of the delay of menstruation, the suspicion of ectopic should be strongly in our minds and a careful pelvic examination should be made.

It has been stated that in the early death of the fetus the symptoms of ectopic gestation may be so mild, that among women not accustomed to noting abnormalities, unless of a severe character, many such conditions go unoperated on. The small effusions in the pelvis and tube may in such instances be absorbed without the patient seeking advice or the true nature of the condition being recognized. This I believe to be undoubtedly true.

In Farrar's paper, in which the histories of 309 consecutive extra-uterine pregnancies were examined, 123 were private patients and 186 were hospital. In my own series, 44 were private and 55 were hospital patients. The ratio of ward patients to private patients should have been much greater and it proves unquestionably that many do not seek relief unless severe symptoms arise.

The old "pelvic hematocele" with its expectant treatment of forty years ago we know to be ruptured ectopic. While many of these women died and the large majority of the remainder were made invalids for life, yet some of the milder types made good recoveries. Lawson Tait, in 1883, blazed the way for complete recovery by operating for ruptured tubal pregnancy. While patients may, and do, recover without operation from the milder types, the danger of such conditions is grave, on account of the possibility of continued hemorrhage. The operation itself is far safer than the risk of waiting and inaction assumed by the patient.

The diagnosis of tubal pregnancy can be made in the majority of cases, yet there are cases in which the examiner must confess a doubt in his own mind.

On account of the immediate and changing pathological condition present, there can be no constant symptoms existing in all cases. In early cases, when the impregnated ovum is still viable and there is no leakage in the pelvis, our only symptom is that of pain in a varying mild degree, due to the distention of the tube by commencing hemorrhage.

When this is associated with a delayed menstruation, a pelvic examination is necessary. When the escaping blood in the tube has been sufficient to cause the separation of the chorionic implantation and death of the fetus uterine flowing commences, adding another diagnostic sign, which is probably the most constant of all symptoms of tubal gestation. Even this is absent, however, in some of our most serious cases, in which the erosive action of the villi has been sufficient so to weaken the tube wall as to permit of rupture and profuse abdominal hemorrhage—the first symptom to call the patient's attention to her serious condition.

These occurrences are fortunately not common, and our continued reliance on the abnormal persistent uterine bleeding, associated with localized pain of a new kind, as diagnostic signs to awaken our closer questioning and more careful examination, will not carry us far astray.

To the patients giving classical symptoms as depicted in every text, I will not refer, for here the "going is good," and the diagnosis is practically certain.

THE IMPORTANCE OF THE HISTORY IN THE DIAGNOSIS OF SURGICAL AFFECTIONS OF THE RIGHT UPPER QUADRANT.*

BY CHARLES GORDON HEYD, B.A., M.D.,

NEW YORK.

PROFESSOR OF SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

(From the Surgical Department of the New York Post-Graduate Hospital, Dr. John F. Erdmann, director. The material and cases upon which this paper is based are from the collective surgical service of the department.)

THE primitive gastrointestinal tract is a simple tube occupying a midline position. Embryologically it is divided into three portions—the foregut, the midgut and the hindgut. Anatomically, the stomach, duodenum, liver, biliary ductal system and pancreas are derivatives of the foregut, and in this alimentary segment every digestive enzyme is secreted and the mechanical processes of digestion carried out.

Our physiological conceptions of the stomach have undergone a rather extensive revision since the day of Beaumont. We may conceive, however, of the stomach as exercising primarily two important functions, that of secretion and that of motion. Contrary to the usually accepted idea of gastric physiology, the terminal portion of the stomach is alkaline, and in the fasting or resting phase of the stomach there is a reflux of duodenal material into the antral portion of the stomach, the acidulation and acid digestion of stomach contents taking place in the proximal two-thirds.

In interpreting the symptoms that arise from disturbances of the gastrointestinal tract we should have firmly in our minds two fundamental conceptions, one called by Bayliss the "law of the intestine," which states that stimulation of any part of the intestine leads to contraction above and relaxation below. This is a general law and is applicable to the entire alimentary canal. Essentially it means that under normal conditions contraction in one place is associated with relaxation just below. Meltzer called this the law of contrary innervation. The second fundamental conception is what is called the "law of average localization," which explains why visceral pain is most accurately located in viscera which do not move, such as gall bladder, esophagus, duodenum, ascending and descending colon, and rectum, and less accurately in the more freely movable organs, such as the small intestine and stomach. The brain learns to localize sensations in the area of the average position of the part from which they originate. The importance of these two laws in the interpretation of the symptomatology of abdominal conditions is very great, and we must recognize that disturbance of one part of the alimentary tract may manifest itself by symptoms in some distant portion.

Probably the most frequent symptom numerically in abdominal conditions is that of dyspepsia. The stomach, by reason of its muscular apparatus and rather close proximity to the outside world by way of the esophagus, may be spoken of as the voice of the upper abdomen, and malfunction of the upper intestinal tract induces quite early the symptoms of indigestion. Again, dyspepsia is one of the most common reflex disturbances of general constitutional disease. The elaborate statistical work of Cabot classifies indigestion, in so far as the etiological factor is concerned, as follows: (1) Tuberculosis, (2) cardiac disease, (3) affections of the kidney, (4) neuroses and psychoneuroses, (5) nephritis; while dyspepsia from exhaustion, debilitation, industrial overstrain and alcoholism are so commonplace as to be beyond statistical computation. The classification of causes of dyspepsia from large clinics has shown that of 100 persons complaining of indigestion, approximately 40 per cent. have the cause of their dyspepsia in organs entirely remote from the abdomen, while 40 per cent. have the etiological factor within the abdomen, but remote from the stomach, and less than 20 per cent. have actual organic disease of the stomach. The last decade has witnessed the gradual reduction in the number of the so-called neuroses of the stomach with an extension of the organic causes of stomach disease. As a very commonplace example of indigestion from causes entirely remote from the abdomen one has only to recall that approximately 10 per cent. of all cases of locomotor ataxia have been operated upon for a supposed abdominal condition and usually for a supposed ulcer of the stomach, gall-bladder condition, or a diseased appendix. For practical purposes, when we consider ulcer of the stomach, cancer of the stomach, affections of the biliary system, and disease of the appendix, we will have considered 95 per cent. of the surgical affections of the abdomen. We believe that in the symptomatic evolution of each

*Read before the Luzerne County Medical Society, Pocono Manor, Pa., Wednesday, June 22, 1921.

of these conditions there is, as a rule, a clear-cut and distinct picture, and that the history, properly interpreted, will lead to the correct anatomical diagnosis in at least 90 per cent. of the cases.

The appendix in the adult has a very definite anatomical conformation. It is a blind tube with its narrowest portion at the cecum, known as the valve of Gerlach. It is essentially an organ with a terminal blood supply, except in 16 per cent. of females, where there is a connecting artery to the right ovary. It has a strong submucous layer which represents the distention strength of the appendix. This submucous layer is absent in children, and hence accounts for the ease of perforation in children. We believe that the symptomatology of acute appendicitis is one of the most fixed and well ordered of all abdominal conditions. Its symptomatology is precise and, within the first 24 hours of its evolution, embraces the following chronological order of symptoms: (1) Pain; this pain is epigastric, confined to the region of the navel, and is colicky in type; (2) is followed by nausea or vomiting or both; (3) generalized abdominal sensibility; (4) temperature; (5) leucocytosis and ascending polynucleosis. One can explain this chronological evolution of symptoms by a consideration of the pathological sequence of events in the infected appendix. The infection arises on the mucosa in 95 per cent. of cases; it is associated with tumefaction and intumescence and we have an angulation of the appendix with occlusion of the lumen or occlusion of the lumen at the valve of Gerlach. At this stage we have essentially an empyema, and the products of the infection are retained within the lumen of the appendix under pressure. One of three things occurs: (1) Gangrene of the appendix; (2) rupture, or (3) resolution by intracecal drainage of the contents of the appendix. These pathological states distinctly parallel the symptomatology. At the time the infection begins in the appendix we have a point of irritation below the small intestine and we have a disturbance of the law of the intestine with the small intestine participating in an exaggeration of its normal peristaltic activity. As a result we have colicky epigastric pain from hyperactivity of the small intestine. The exaggeration of the function of the small intestine brings about generalized abdominal sensibility, and the activating agent in this trend of events is an infective process which produces the constitutional reaction of temperature, leucocytosis, and polynucleosis. At the end of 18 to 24 hours the infection of the appendix has progressed to such a point that there is a periappendicitis with exudation or extravasation of appendiceal contents and the clinical picture is changed. The pain becomes constant, not colicky, is confined to the right lower quadrant, associated with local tenderness and spasticity over McBurney's point, while temperature may or may not be elevated. The leucocytosis and polynucleosis, however, remain present.

Turning to chronic appendicitis one is confronted with an entirely different evolution of symptoms. Here we have an affection that disturbs the rhythmic working of the law of the intestine in that contraction is followed by relaxation. The most typical example of this neuromuscular mechanism is found at the cardiac, pyloric, ileocecal, and anal sphincters which normally relax as peristaltic waves come to them. The presence of a minor degree of irritation in the appendix brings about a disturbance in the neuromuscular apparatus of the ileocecal valve and pylorus. Barclay has shown that spasmodic closure of the pylorus follows stimulation of the terminal ileum. At the ileocecal valve we have a great biological partition. Here the chemical reaction of the intestinal contents changes, the bacterial flora reaches its maximum development, the fluidity of the contents is at its greatest, there is an anistalsis rather than peristalsis, and this is the place of predominant lymphoid tissue development within the abdomen, together with a natural point of stasis or delay. The history, then, of chronic appendicitis is characterized by variability and lack of that precision which characterizes acute appendicitis. There stands out, however, in the history of these patients almost invariably the history of an acute attack, and one is surprised to find on checking up "after results" that the cases that complained only of pain in the right lower quadrant have uniformly not been cured by the removal of the appendix, but that the cases that complained of atypical dyspepsia due to a supposedly diseased appendix have been almost uniformly cured of their distress by an appendectomy.

If disease of the gall bladder and stomach can be eliminated, then it is ordinarily possible to make a diagnosis of appendicular dyspepsia. A chronically infected appendix produces epigastric distress of indefinite intermittency. The symptoms are those of pain and distress more prolonged than similar occurrences in disease of the gall bladder, with increased acidity, vomiting, and eructations of sour material. Articles of food which at one time are associated with indigestion are eaten at other times with zest and relish. There is a long interval between the attacks in which the patient is free from symptoms. Each succeeding attack has a tendency to be more severe than the previous one by reason of the increased stenosis and stricture of the lumen of the appendix after each exacerbation. We believe that these symptoms are due to pylorospasm associated with hyperactivity and hypersecretion of the stomach, and may be designated as the pyloric syndrome of chronic appendicitis. This variability in the indigestion from disease of the appendix has been emphasized by Moynihan, who states that the most frequent site for the production of the symptoms of ulcer of the stomach is in the right lower quadrant.

It must not be forgotten that chronic disease of the appendix may occasion a rather severe hematemesis. Hutchinson records 24 cases of fatal hemorrhage from the stomach after operations of various kinds upon the abdominal viscera. Of these 24 cases, 21 were cases of appendicitis with septic complications. I have records of 4 cases of pronounced gastric hemorrhage which, on very extensive abdominal exploration, revealed no morbid process except in the appendix and, following an appendectomy, there was a cessation

of the gastric distress and gastric hemorrhage. Gastric hemorrhage has been experimentally produced by Rogers by injecting chemical irritants into the cecum and ascending colon, while irritation of the colon, per se, has been shown to bring about a gastric stasis and the delayed passage of food material through the small intestine.

In disease of the biliary system we are confronted with a pathologic and symptomatic sequence of events that is rather characteristic and definite. The basis from the production of symptoms is essentially due to infection in the gall bladder whether stones are present or absent. One recalls the rather high percentage of hepatitis that coexists with chronic cholecystitis, and the relationship of pancreatitis to disease of the biliary system is so thoroughly elaborated as to require little comment. The end-result of cholecystectomy conclusively demonstrates that the patients are apparently in as excellent condition of health after cholecystectomy as before, and that, so far as the general metabolic processes of the body are concerned, the presence or absence of the gall bladder is not of much importance.

If one made a study of a sufficiently large number of cases of biliary disease he would find that he could catalog the patients into four distinct clinical groups: (1) Those that complain of indigestion only (2) those that give a history of acute attacks of biliary colic, with or without preceding indigestion; (3) those that give a history of biliary colic and also the history of jaundice; (4) those who give any of the above histories and develop the complications of biliary disease—carcinoma, pancreatitis, duodenobiliary fistula, etc.

The early symptoms of cholecystitis, whether calculous or non-calculous, are the symptoms of an indigestion of which the chief complaint is gas in the stomach. For a variable period of time these patients complain of a sense of weight and fullness in the stomach, present after small meals and relatively worse after large meals. Upon belching gas there is obtained some relief, and a not uncommon history is that of a patient leaving the dinner table and inducing vomiting with complete amelioration of symptoms. The gas production is in a measure dependent upon the quality of the food—carbohydrates, fats, starches, nuts, and some fruits induce a greater degree of gas production. These patients are treated for nervous indigestion or gastritis when they have a chronically diseased gall bladder with thickened walls and a loss of the normal distensibility of the gall bladder. Into this history there may ensue at a later period or without this history of indigestion the first indication of biliary trouble is ushered in by an attack of acute, sharp, agonizing pain which comes on like a stroke of lightning, is of maximum intensity, and is associated with restlessness and movement upon the part of the patient. There is a strong desire to lean over a chair or to grip the lower portion of the thorax. With this is usually associated nausea and vomiting. The attacks of pain have a predilection for nocturnal occurrence and are so severe as to require hypodermics of morphine for their control. The characteristic and outstanding feature is the lightning-like onset of the pain, without premonition or warning, and its intensity requiring morphine. After four to eight hours the pain disappears almost as rapidly as its onset, leaving behind a residual soreness along the right costal margin. The third clinical group is characterized by a history somewhat after the fashion of the preceding types, with the exception that after an attack like the above they find themselves jaundiced, and in this group we have a trinity of symptoms—colic, jaundice, and sepsis—cholangitis. This jaundice is associated with colic and usually with chills, fever, and sweating and for many years masqueraded under the title of Charcot's intermittent hepatic fever and was variously ascribed to malaria.

Jaundice is a symptom of sufficient magnitude to make the patient apprehensive. If one considers the diagnostic possibilities of jaundice he will find that aside from catarrhal jaundice—a condition founded upon insecure pathological information—which is characterized by slight constitutional disturbance and uniformly resolves and clears up in four to six weeks, we have essentially a differentiation of jaundice produced by neoplasms and the jaundice produced by calculous disease of the biliary apparatus. Stupor is only associated with jaundice in cirrhosis and acute yellow atrophy, while emaciation is uniformly present in all types of chronic jaundice, irrespective of the etiological factor. The onset of jaundice with colic predicates an infective process, and, since 98 per cent. of all gallstones have had their origin in infective changes in the gall bladder, we find that the gall bladder in chronic calculous cholangitis is atrophied, thickened, or undergoing fibroid contracture and is non-palpable on physical examination unless there is an accidental occlusion of the cystic duct with hydrops of the gall bladder.

Calculous cholangitis predicates a chronic cholecystitis with cicatrization and contracture. In 187 cases of obstruction of the common duct reported by Courvoisier, in 100 obstruction was due to causes other than stone, and in 87 the obstruction was due to calculous impaction. Of the 100 cases in which obstruction was due to causes other than stone, in 92 there was a dilatation or distention of the gall bladder and in 8 cases there was a normal gall bladder or an atrophy of the gall bladder. Of the 87 cases in which obstruction was due to stone, in 70 cases the gall bladder was atrophied and in 17 cases the gall bladder was dilated. Courvoisier then enunciated his law: "In cases of chronic jaundice due to blocking of the common duct a contraction of the gall bladder signifies that the obstruction is due to stone; a dilatation of the gall bladder that the obstruction is due to causes other than stone."

In 84 per cent. of cases with stone in the common duct we find a contracted gall bladder. Therefore, a case of obstructive jaundice with (1) history of colic, (2) distinct variations in the intensity of the jaundice (remittent and intermittent) "ebbs and flows," (3) absence of distention of the gall bladder, (4) presence of septic reaction—chill, fever, sweat, leucocytosis, (5)

chronicity—the diagnosis is almost positively calculous cholangitis.

The jaundice that is due to extrinsic encroachment on the common duct is due ordinarily to neoplasms. It comes on slowly, imperceptibly, deepening day by day, and neither remits nor intermits, but becomes progressively deeper in color until it becomes a typical black jaundice—icterus melas. Its development is without pain until late, and without temperature, so that the evolution of the jaundice of malignancy is decidedly distinct and separate from that of jaundice associated with biliary disease.

Ulcer of the gastroduodenal segment is located anatomically in three main places: (1) In the silent area of the stomach with no pyloric involvement; (2) on the pyloric segment with obstruction from spasm or invasion; (3) in the duodenal segment. Eighty-eight per cent. of all ulcers are characterized by a regular and uniform symptomatology and three symptoms stand out in unusual prominence: (1) Pain that bears some relationship to the time of ingestion of food; (2) chronicity—the symptoms extending over a considerable period of time, and (3) periodicity—in that the symptoms recur in exact similarity day after day with almost unvarying precision. Eighty-five per cent. of all ulcers of the stomach are situated on the pylorus, antrum, or the adjacent three-fourths of the lesser curvature, and it is the regularity in the symptomatology of ulcer that makes the diagnosis possible. A loss of the periodic element with symptoms which suggest ulcer makes one suspicious of malignancy, for 99 per cent. of malignant growths of the stomach show an absence of periodicity in their symptomatology. Depending upon the localization of the ulcer we have certain specific features that go with each one. The ulcer in the silent area of the stomach is, as a rule, characterized, in addition to the above-mentioned symptoms, by the early habit of vomiting, the vomiting of undigested food with a tendency to be blood-streaked. The pyloric ulcer has early induced in its symptomatology a motor insufficiency with stagnation of gastric contents and vomiting of large quantities of retained gastric content and food remnants of a previous day's ingestion. The duodenal ulcer has characteristically added to these three major symptoms nocturnal occurrence, usually after 12 p. m., and the complete alleviation of symptoms upon the ingestion of food, while all three types of ulcer acquire early and independent of the physician's advice the bicarbonate of soda habit.

The ulcer near the cardia frequently, but not invariably, produces pain almost immediately after the ingestion of food; the ulcer at or near the pylorus from an hour and a half to two hours, while the pain in duodenal ulcer is much more constant in the time of onset, being between two and a half to three hours after a meal.

There are no symptoms which are pathognomonic of cancer, and at the time that one most desires to make a diagnosis of cancer there is no outstanding clinical picture that renders this possible. The presence of carcinoma of the stomach is made known only when ulceration occurs or when there is an interference with the evacuation of the stomach contents. In general, carcinoma of the stomach manifests itself early by mechanical factors rather than by changes in chemistry. Cachexia is one of the most prominent symptoms, being present in approximately 85 per cent. of cases that are diagnosed as carcinoma. A palpable tumor exists in about 58 per cent., food remnants in 65 per cent., and pain is present in over 85 per cent. of cases. We find cancer of the stomach clinically portrayed by three quite distinct types of history: (1) The first group, constituting about 60 per cent., occurs in patients who have had a history of gastric distress covering at least a period of eight to ten years. This previous gastric history entitles us to believe that the patient was suffering from chronic gastric ulcer. There were repeated attacks of pain occurring day after day, with a time relationship to the ingestion of food and with a periodic reproduction of the same symptoms day after day. Into this history there comes one attack from which the patient does not recover or does not respond to a form of medical treatment that has heretofore proved beneficial. The pain becomes constant, marked distaste or aversion to food is acquired, blood is constantly present in the stool and the patient has a duration of cancer symptoms of six months. The second group constitutes 30 per cent. and occurs in the type of man who has been previously perfectly well. He has an attack of gastric distress which suggests an acute ulcer of the stomach, with or without hemorrhage. At the end of a few months the man has lost physically beyond anything that could be expected in a simple ulcer, and all too soon a progressive anemia and emaciation and beginning cachexia make known the diagnosis of rapidly growing carcinoma; his cancer symptoms average about eight to ten months. The third group is represented by approximately 10 per cent., with the history that is suggestive of simple ulcer from which he nearly recovers, but never quite wholly, and after a variable period of time—14 to 18 months—slowly but progressively becomes worse, acquires a marked aversion to food, and progresses into the well-defined cachexia of malignancy.

DETAILS IN DERMATOLOGY.

By Charles Mallory Williams, M.D.,

New York,

Attending Physician, New York Skin and Cancer Hospital; Professor of Dermatology, University of Vermont; Associate Professor of Dermatology, New York Post-Graduate Medical School and Hospital.

It has been well said that more mistakes in diagnosis are due to carelessness than to ignorance, and this is as true in dermatology as in any other branch of medicine. Of course, there are cases where the diagnosis is evident at a glance, but even here careful examination may reveal special features which will be of the greatest value in treatment. Do not be deceived by the patient's statement, "The only spots are those on my hands—there is nothing at all on the rest of my body." It is probable that he is trying to tell the truth, but it is also probable that he is mistaken, and

if there is any reason to believe that the eruption is more extensive than the patient has indicated, or if the lesions shown are not absolutely characteristic, make a complete examination. It is also important to approach any problem in diagnosis with an open mind. In Prof. Trimble's service at the University and Bellevue Medical College it used to be the custom to enjoin absolute silence on the patients until the examination was completed, and this rule should be followed as far as possible in both public and private practice. It removes, indeed, a valuable source of information, though only temporarily, but it often avoids also a great deal of misinformation. What is much more important, it teaches observation as nothing else can. It is seldom necessary, for instance, to ask if an eruption itches—tell-tale scratches are there at least ninety-nine times in a hundred. A very shrewd estimate can also be made of the duration of the process in most instances. Acute congestion, vesicles, pustules denote a continuing process, and if these alone are present the eruption is fairly recent. Stains and scars, on the other hand, indicate a considerable interval since the first outbreak, and from the color one may infer whether the interval is to be measured in weeks or months or perhaps years. This estimate is often more reliable than the patient's statement. For instance, in a small epidemic of tinea circinata, derived from cats, one of the patients showed me a lesion nearly as large as the palm of the hand, with typical clearing center and advancing border, which she told me had been present less than twenty-four hours. It must have been there a week, but she had not noticed it. After the investigation has been pushed as far as possible by examination alone, questions may be asked, and in some cases the diagnosis will rest on the answers received, though this is rarely the case in dermatology.

The first thing to be noted after stripping the patient is the distribution of the lesions. The individual lesion of scabies, for instance, may be indistinguishable from an inflamed follicle or the papulovesicle of eczema; the diagnosis is made by observing the parts affected. Next, note the presence or absence of a tendency to form groups and the arrangement of the lesions in each group. Are they all of the same age? Is the process most active at the center or at the periphery? Is the margin sharp or vague and indefinite? If the margin is well defined, is it a continuous band, or composed of separate elements which tend to coalesce? Is the skin between the active lesions normal, or is it congested, stained, or infiltrated? The next step is to determine the elemental lesion of the eruption, whether erythema, papule, or vesicle, and to trace it through its evolution to its healing. The elemental lesions are usually found at the periphery; where the disease is most active, the lesions may be too far advanced or too closely set to help much in a diagnosis.

The trained touch may be of almost as much help as the sight. A papule may look solid, but prove to be soft under the finger, while the size, contour, and consistency of some of the deeper lesions can be determined by the touch alone.

Lastly, the laboratory tests. These are at times the only way of establishing a diagnosis, as in some forms of tinea of the hands and feet, and are always a great help, but laboratory tests can never replace clinical observation. A Wassermann reaction which is persistently positive may prove that the patient has syphilis, but it cannot prove that the lesion which you are studying is syphilitic. Take, for instance, a carcinoma of the tongue developing on a syphilitic glossitis or an ulcerated gumma. To rely on a positive Wassermann and give antisyphilitic treatment only is to condemn the patient to death. To perform a biopsy and await the report of the microscopical findings is to open channels for metastases, no matter how short the interval between biopsy and operation.

If it is true that carelessness is responsible for most of the errors in diagnosis, it is equally true that a large proportion of the errors in treatment are due to lack of precision in the directions given by the physician.

In cases of skin diseases, in particular, the laity are profoundly ignorant of what to expect; they generally expect a single visit and the use of a prescription for a week to work a prompt cure. Of course this is incorrect. The majority of skin diseases are notoriously chronic, and the patient should therefore be warned that he must be content to progress slowly and that perseverance on his part is quite as important as skill on the part of his physician, and indeed is essential to success. Many diseases also—notably eczema—are prone to recur after apparent cure, and the patient should be warned of this also and instructed to watch for the first sign of a fresh outbreak, and to report it at once to his physician. If a patient can be made to realize these simple facts he is much more apt to persist in treatment, and it is only by persistence that he can hope to recover. The worst offenders in this respect are probably the syphilitics of the poorer classes, who generally cease treatment as soon as the visible signs of the disease are removed and who therefore suffer from constant relapses, especially in the tertiary stage.

But perseverance in treatment is not, by itself, enough, for the character of the disease changes from time to time, partly because of its natural evolution, partly as a result of therapy, and to meet these variations the treatment must not only be persevered in but must also be altered from time to time. The physician knows this, of course, but the patient doesn't know it unless he is told, and if he doesn't know it he will persist in measures that have become useless or even harmful, and then seeing no further improvement he is apt to abandon treatment altogether, or perhaps seek another physician. The treatment which is efficacious in acute eczema, for example, is valueless in the chronic types; that which is beneficial in chronic cases may be harmful in an acute exacerbation. The patient must be made to realize this and that repeated visits to the physician are therefore essential. In acne, also, treatment must be varied. The local applications must be strong enough to produce a slight exfoliation but not strong enough, in ambulant treatment, to produce a severe dermatitis, and the only way to de-

termine the strength required by each case is by trial. When the comedones cease to form the exfoliating treatment is no longer indicated—but the patient cannot be expected to know this intuitively.

It is folly to give a patient a prescription for a salve or lotion, saying only, "Use this twice a day." An amusing instance of this came to my notice some years ago. A poor woman suffering from some uterine disorder was told to use salt dissolved in hot water. There was no improvement, and questioning by the visiting nurse revealed the fact that the woman had dissolved the salt in hot water, as directed, and then had soaked a sheet in the solution and sat down upon it! Take it for granted that your patients know nothing, absolutely nothing, about the correct method of local applications. In the treatment of acne, for instance, there is no better preparation than the familiar lotio alba—but it must be properly used and properly made. I have even known druggists, unfamiliar with the preparation, to filter out the precipitate, which is the active part. Instruct your patient always to shake the bottle before using, to pour out only what is required, to sop it on with a clean cloth and not to use a sponge or absorbent cotton, as these two would hold the powder in their meshes, instead of leaving it on the face. Warn also against rubbing; say definitely that it is to be sopped on, not rubbed on. And tell exactly the hours when it is to be used. Explain that the powder is the active ingredient and that the longer it is left in contact with the skin the better. It takes time to give such minute directions, but they are the secret of success. In using a stimulating and antiseptic lotion on the scalp, on the other hand, rubbing is essential, and it should be explained to the patient that mere wetting the hair will not do. It is the same with salves and pastes—for protection or for mild action they are smeared on, for penetration and vigorous action, rubbed in. The patient doesn't know which is indicated, and he must be told. He must be told also how much to use. For instance, a very little sulphur cream, properly applied, may be sufficient for the entire scalp, while if a subacute eczema is to be treated with Lassar's paste, a thick layer must be applied and left on. In the inunction treatment of syphilis it is, of course, essential that the dosage be regulated—yet I have known patients use half an ounce or less of mercurial ointment in a week, for lack of proper directions, and to make the application to the same part of the body repeatedly, because the reason for using different parts had never been explained to them.

One would think that anyone would know how to use tincture of green soap for a shampoo, yet I have known patients to declare that they could get no lather with it and that it always left the hair sticky. The only explanation I can think of is that they were deceived by its liquid character and did not use enough water either in shampooing or in rinsing afterward. Tell your patients therefore that after shampooing the hair should be rinsed till the water comes away perfectly clear.

These may serve as examples, but the principle is universal. Thoroughness in observation is essential to a correct diagnosis, and minute instructions as to details of treatment are essential to successful therapy. In some cases it is even advisable to make the patient repeat the instructions, in order to be sure that they are understood. It has been said that genius is the infinite capacity for taking pains. Whether this capacity is all that is required to constitute genius may be questioned, but it will certainly carry a man a long way in the practice of medicine, or of any other profession.

4 West Fiftieth Street.

CHRONIC NEPHRITIS WITH BENCE-JONES PROTEINURIA.

EFFECT OF RADIUM EXPOSURES ON QUANTITATIVE OUTPUT OF BENCE-JONES PROTEIN.

By WALTMAN WALTERS, M.D.,

ROCHESTER, MINN.

FELLOW IN THE MAYO FOUNDATION.

In 1847 Henry Bence-Jones reported the incidence of a peculiar type of protein formed in the urine of a patient of whose condition he had made a diagnosis of osteomalacia fragilis rubra. The reactions of the protein which distinguished it from serum albumin were its precipitation from an acid urine at 56° C, its dissolution on boiling, and its reappearance again on cooling. At necropsy the ribs cut with the greatest ease and the bodies of the vertebrae could be sliced off with a knife. The kidneys were reported to have been sound clinically as well as when examined microscopically.

In more than 200 cases of Bence-Jones proteinuria which have been reported since 1847 satisfactory evidence of renal insufficiency has been reported in but four cases[1,2,3,4] in only one of which[3] was there a "damming back" of Bence-Jones protein in the blood stream. Folin and Dennis have noted the frequent occurrence of a few hyaline and granular casts in cases of myeloma without clinical evidence of nephritis.

A case of Bence-Jones proteinuria is reported here in which there was definite evidence of progressive renal insufficiency denoted by extremely low excretions of phenolsulphonephthalein and the retention of large amounts of uric acid, urea, nonprotein nitrogen, and creatinin in the blood. The effect was studied of radium exposure over two inguinal masses which may have been the primary causative factor in the production of the Bence-Jones proteinuria. This is the fourth case of Bence-Jones proteinuria which was discovered in the examination of 31,487 patients by the members of the staff of the Mayo Clinic during the period from June 20, 1920, to March 2, 1921.

Case 351167. Mrs. C. D., aged 42, entered the Clinic March 2, 1921. She had not been well since an attack of influenza two years before. Shortly after this attack she missed two menstrual periods, but she does not believe that she was pregnant. During this period she lost considerable weight. In May, 1920, after having urinated on the ground, she noticed that a yellow milky material remained on the surface, which she believed was due to drinking alkaline water; as she felt well she dismissed the fact from her mind. Three months later, after a chill following a wetting, she noticed stiffness of the neck which persisted. During the fol-

lowing two weeks she had a polyarthritis, which first involved the right shoulder joint, later the wrist joints, and finally the left shoulder joint. These joints were painful on motion, and the periarticular tissues were red and swollen. Her urine was examined and Bence-Jones protein was discovered. At this time she noticed that her inguinal glands were swollen, but not tender. She gradually lost in weight and strength, and her skin, which had been of a pinkish hue, gradually faded and became brownish. Three weeks before she came to the Clinic a sudden sharp shooting pain appeared in the anterior surface of the right lower leg, beginning at the inguinal fold and extending below the knee. These pains appeared most often when she was in bed, and were of but a few seconds' duration.

Physical examination revealed an under-nourished woman not acutely ill; she weighed 115 pounds. The skin of the entire body was hyperpigmented; the lips and bulbar conjunctiva were pale. The head could not be rotated beyond certain points to the right and left without considerable pain. The tissues about both left and right wrist joints were swollen and somewhat painful on forced movement. A circumscribed fluctuating swelling over the distal end of the left ulna, dorsal surface, was approximately 1 cm. in diameter.

A mass palpable in the left femoral region just above the saphenous opening measured 9 by 8 cm.; a mass in the right femoral region measured 6 by 7 cm. These masses were smooth and indurated, and appeared to be fixed to the rami of the pubic bones. A few small glands were felt in both inguinal regions. Roentgenograms of all the bones did not reveal evidence of a pathologic condition; the masses failed to cast a shadow. The blood Wassermann reaction was negative. The systolic blood pressure was 124, the diastolic was 80. Repeated blood counts showed the marked secondary anemia characteristic of patients with Bence-Jones proteinuria. In addition, the relative increase in the percentage of small lymphocytes was marked. (Table 1).

TABLE 1.

BLOOD PICTURE (CASE 351167).

	March 7	March 10	May 21*

*Blood count made by Dr. G. F. Gibson, Fort Dodge, Iowa

Repeated two-hour specimens of urine examined quantitatively for Bence-Jones protein, by a slight modification of the method of Folin and Denis, showed a constant excretion of from 2 to 3 gm. every twelve hours, with the patient on a general diet. The excretion was the same during the twelve hours of night as the twelve hours of day.

Bence-Jones proteinuria occurs in 80 per cent. of all cases of myeloma; it has been reported by Askanazy and Decastello to have been present also in three cases of lymphatic leukemia. Since the patient (Case 351167) had a history of enlargement of the inguinal glands and from 42 to 51 per cent. small lymphocytes by the differential blood count we wished to have a microscopic section removed from one of the femoral masses to aid in the diagnosis, but this was refused repeatedly. We believed radium exposure over the femoral masses, whether they were bone tumors or evidence of early lymphatic leukemia, to be a logical procedure. Therefore, 3,000 mg. hours were given, equally divided between the left and right masses, and the amount of Bence-Jones protein excreted was estimated daily. The first radium exposure, March 11, and the second, March 15, lasted for twelve hours. There was little, if any, constant reduction in the quantity of Bence-Jones protein excreted in the sixty-four day period following the exposures (Tables 2 and 3). The day after the first exposure the patient had a moderate general reaction, with loss of appetite, nausea, and the desire to vomit. The next day the patient complained of headache and a feeling of depression, but this gradually disappeared in twenty-four hours. There was no reaction following the second exposure.

Repeated examinations of the urine failed to show serum albumin, casts, or erythrocytes; an occasional leucocyte was found. The specific gravity of both night and day specimens of the urine varied from 1.010 to 1.020. A phenolsulphonephthalein functional test was made March 4, and but 10 per cent. of the dye was recovered at the end of two hours. The test was repeated March 12, and but 7 per cent. of the dye was recovered. Because of this extremely low phenolsulphonephthalein excretion, the patient's blood was examined for further evidence of renal insufficiency and values of 3.24 mg. uric acid, 3.3 mg. creatinin, 74 mg. urea, and 63 mg. nonprotein nitrogen were found for 100 c.c. Blood taken six days later showed an increase in the uric acid

to 5.4 mg., of the urea to 109 mg., of the creatinin to 7.5 mg., and of the nonprotein nitrogen to 86 mg. for 100 c.c. (Table 4).

TABLE 4.
RENAL FUNCTIONAL DETERMINATIONS.

	Normal figures	March 4, 1921	March 12	March 14	March 19
Phenolsulphonepthalein test (2 hours), per cent	50 to 70	10	7	....	....
Blood uric acid per 100 c.c., mg.	2.5	....	....	3.24	5.4
Blood urea nitrogen per per 100 c.c., mg.	20 to 45	....	....	34.5	51
Blood creatinin per 100 c.c., mg.	2	....	....	3.3	7.5
Blood nonprotein nitrogen per 100 c.c., mg.	21 to 40	....	....	63	86

Because of the renal complication we believed that we could do little to change the course of the patient's disease and she was sent home to her family, with the request that she send us occasionally twenty-four hour specimens of urine for analysis. In these analyses little variation in output of the Bence-Jones protein has been found up to May 18, 1921 (Table 3). The patient consulted Dr. Gibson May 21. She refused to have a phenolsulphonephthalein test or to have any blood removed for functional examinations. Her systolic blood pressure was 150, the diastolic 70; the eye grounds were negative. Her husband states that the masses in the femoral regions are larger than before the radium exposure, that she has felt a great deal weaker, and has had frequent attacks of nausea and vomiting.

After a definite renal insufficiency had been proved a portion of the patient's blood serum was examined for Bence-Jones protein, by the method described by V. C. Jacobson, in which 10 c.c. of serum is kept at 58° C. for thirty minutes. A dense milky precipitate was removed by filtration. Four cubic centimeters of 10 per cent. sodium carbonate run over the filter paper dissolved the precipitate, a portion of which was added to 10 c.c. of normal urine. To this 1 c.c. of concentrated hydrochloric acid was added; a cloudiness appeared which became more pronounced at 60° C., and disappeared at 100° C. The amount of precipitate obtained was so small that no attempt was made to estimate its quantity.

The patient died August 19, 1921. Consent for necropsy could not be obtained.

Summary.—1. This case is of interest because it shows clearly a renal insufficiency of a marked degree appearing in a patient with Bence-Jones proteinuria, with a retention of the protein in the blood stream.

2. Radium exposure over two femoral masses caused no reduction in their size or in the amount of Bence-Jones protein excreted in the sixty-four days following the exposure.

A CASE OF PERMANENT HOMONYMOUS HEMIANOPSIA FOLLOWING AN ATTACK OF MIGRAINE.

BY ALFRED WIENER, M.D.,

NEW YORK.

THE occurrence of an organic lesion in the brain, during or following an attack of migraine, has been reported by various writers. Some have reported aphasia, others cerebral palsies, and still others a permanent hemianopsia. It is the occurrence of a permanent hemianopsia in a patient of mine which has prompted me to place this case on record.

Such types occurring in young people are uncommon. Up to the present time, no satisfactory explanation has been offered just why such lesions should occur. In older people in whom arterial disease exists one might naturally expect that migraine might precipitate such a lesion.

In the transactions of the *Ophthalmological Society of the United Kingdom*, xxxiii, 1913, p. 138, A. W. Ormond reports two cases of permanent hemianopsia occurring after severe attacks of migraine. A short abstract of these cases follows.

CASE 1.—A female, aged 33 years, was subject for ten years to severe migraine. An unusually prolonged attack, lasting for three or four days, was followed by inability to see anything on the right side. The vision in both eyes is 6/6 with correction. The fundi are normal. The defect in the field is not absolute. The condition of fields has been stationary for five months, the date of the last note.

CASE 2.—A female, aged 52 years, had suffered from bilious headaches since she was eighteen years of age. When three months pregnant she had headache followed by sickness on July 20, July 27 and August 3. On the morning of August 4 she awoke with a headache and later in the day, after running to catch a train, found she could see nothing on the left side. On examination it was found that the vision in the right eye was 6/5 and in the left eye 6/6. Homonyous hemianopsia involving the left side of the field of vision was present. The fundi were normal. The Wassermann reaction was negative, and nothing was found wrong in the patient's general physical condition. Thehemianopsia was still present when examined seven months later.

The author offers as an explanation the occurrence of an arterial spasm of that branch of the posterior cerebral artery which supplies the visual centre. This results in a permanent interference with the visual function of that side, and so leads to blindness on the opposite side. In the *Neurolog. Centralblatt*, 1903 vol. xxii., entitled "Eine merkwürdige Complication eines Migraine-Falles," Hoeflmayer reported a case in a woman 57 years of age. The condition lasted one month, and then cleared up. He thought the condition a toxic one added to a neurasthenic exhaustion. Hysteria was ruled out. The cases reported by Fere, Charcot, and Infeld are such as make one believe that there existed organic lesions of the brain, in which migraine appeared as a symptom pure and simple.

In the *Journal of Nervous and Mental Diseases*, vol. xxxiv., 1907, J. J. Thomas reports three cases occurring in younger individuals.

Case 1.—A young woman, 30 years of age, had suffered for some time from periodical attacks of headache. After mental strain and worry, a severe headache followed by vertigo and loss of consciousness occurred. On the next day she suffered severe frontal headache with general numbness on the left side of the body, and slight paresis took place. For the first three weeks there was complete amnesia. She improved rapidly. Mental dullness and a weakness on the left side remained. In addition there was a left hemianopsia. The hemianopsia was permanent.

Case 2.—A single woman, 27 years of age, with neurotic family history had suffered from migraine for ten years. The sudden death of a sister brought on a severe attack. Paresthesia over the entire left side of the body was noticed together with a partial loss of power. This was accompanied by a loss of sight in the left field of vision. She regained her power but a left hemianopsia remained.

Case 3.—This young woman, 27 years of age, had a negative family history with the exception of the father, who suffered from periodical attacks of headache, beginning in youth, and continuing for many years. The patient's headache began at the age of twelve. During one of these attacks, occurring at the time of examination, a right hemianopsia was found. These headaches always occurred about two weeks after menstruation. The patient was free from all other nervous symptoms. A permanent hemianopsia remained.

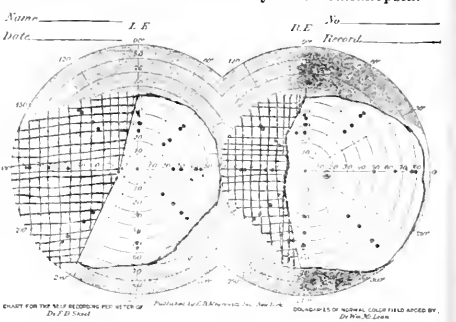
In reference to his own cases, Dr. Thomas says that in the first patient, judging from the history, viz., the father died of apoplexy and the mother of cardiac disease, the absence of heredity, and the nature of the attacks, the lesion might have been due to arterial disease. It is probable that the migraine was no more than an exciting cause for the vascular lesion, and possibly a symptomatic migraine. The second, and particularly the third case, seem to be clearly instances in which we can ascribe the cerebral softening to nothing else than an attack of migraine. In none of the cases was there any evidence of syphilis, kidney, heart, or arterial disease.

In addition to the above recital of cases, I am sure there are others, though I have not been able to find any accurate records of them. I am adding to this list, the history of my own case, which came under my observation at St. Luke's Hospital in the latter part of May.

This patient was a young married woman, aged 40 years. Her illness dated back to only a few weeks previous to the time that I first saw her. Suddenly while at work, everything became unsteady. There were dancing lights in front of her eyes. She could still see the utensils with which she was working. On looking around the room all familiar objects were plainly visible. She was much alarmed and went out into the street. She then found that she could see those objects which were directly in a straight line of vision, but those in the periphery were very indistinct. About two hours following the onset, she was taken with a severe headache. This lasted two days. She knows of no exciting cause, except that she thought it might have been due to the eating of a cake of yeast two hours previous to the time of the onset of the attack. There had been no respiratory, cardiac or gastrointestinal symptoms, and no urinary symptoms. She has been rather constipated of late, but was not previously so. She drinks three to four cups of tea daily; takes no coffee, drugs or alcohol. Previous history: She has been subject to sick headaches for many years. Some similar in character to the last attack of migraine. These have not been so frequent in the past six months. She has had no infectious diseases or operations.

Family History.—Married 17 years. Husband is living and well. Has four children living and healthy. One miscarriage after the second pregnancy. Her father died of fatty heart. Mother is living and well. Had an uncle who died of fits. Menstruation began at ten years of age; always regular and painless. Her period was synchronous with the onset of this attack.

Eye Examination.—Vision of right eye with a —3.00 sph. = 20/20. Vision of left with a —3.50 sph. = 20/30. Pupil ÷ Response to light, accommodation, and consensual reaction perfectly normal. Hemianoptic pupil reaction uncertain. There are no extraocular muscle disturbances. An examination of the fundi reveals nothing of any significance. Both discs are sharply defined and of normal color. The vessels show no anomalous condition and are not diseased. The fields show a distinct left homonymous hemianopsia.



There are no scotomata. An *x*-ray picture of the skull and sinuses showed no abnormal findings.

Our attending physician, Dr. Austin Hollis, who made a painstaking and careful physical examination of this patient, reported the following: "Patient is a well developed and well nourished woman 40 years of age. She is lying quietly in bed and not apparently acutely ill. There is no edema, no petchiae, no jaundice, no cyanosis, no rash, no dyspnoea. The temperature is normal. Posterior cervical, axillary and inguinal nodes can be felt. The thyroid is not palpable. Ears, nose and mastoid region externally are negative. The upper part of the mouth has a plate. The lower teeth are dirty and carious; the gums are retracted and pus is exuding from their edges. The tonsils are not enlarged nor unhealthy looking. The percussion of the heart is normal. There is no thrill, and the place of maximum impulse is normal in location. The heart sounds are regular and distinct. The radials are palpable and the pulse is full and compressible. The blood pressure is 105/70. The lungs are clear throughout to percussion and auscultation. There are no masses to be felt in the abdominal cavity. There is no tenderness. The liver, kidneys, and spleen are not felt. The extremities show no edema. There are no deformities. The biceps, triceps, knee and ankle reflexes are present and hyperactive. There is no clonus, however. There is a suggestive Babinski, Gordon and Oppenheim on both sides.

Urine Examination.—Acid, specific gravity, 1020; albumin, faint trace; no casts; no sugar.

The blood Wassermann was negative. Spinal puncture showed fluid under slightly increased tension; no cells to speak of. The spinal fluid, Wassermann and colloidal tests were negative.

Blood.—Red cells, 4,500,000; white cells, 8,700; differential, 72; eosinophiles, 3; lymphocytes, 25.

Here is a case of a young woman, with no evidence of heart, kidney, or arterial disease. No syphilis nor tuberculosis. All examinations are negative. With the exception of repeated attacks of migraine, this patient has been free from any serious disease or complaints. During a severe attack of migraine she suffers a left hemianopsia from which she at the present time shows not the slightest improvement.

Remarks.—We know that migraine itself does not involve any danger to life. The vascular disturb-

ance however, may in time lead to local vascular degeneration, and this explanation, according to Gowers, may account for the vascular lesions of the brain seen comparatively early in the degenerative period of life. He believes that this is likely to occur in a part of the brain which has been the seat of a periodical functional derangement, like migraine. In my own case we have such a history. Eventually, after a severe attack a permanent hemianopsia remained. As no anatomical changes are known to underlie migraine, the nature of the malady is an inference. Gowers tells us that there are two chief theories which have been held regarding the attacks of migraine. The one is based on the state of the alteration of the blood vessels. As it was found that this condition varied in different people, the Germans, Eulenburg especially, urged that we consider two varieties, viz., the sympatheticotonic and the sympatheticoparalytic. The other chief theory is the one advanced by Moebius and Liveling. They believe that migraine is due to a primary derangement of the nerve cells of the brain. Their function from time to time is disturbed in a peculiar manner, and the visible vasomotor disturbance is of secondary origin. Most authors, I believe, are now agreed to the fact that migraine attacks are due to plain vasomotor disturbances, brought about by some toxemia.

I feel inclined to accept the following explanation in the above case. A vasoconstriction, sufficient to produce an ischemia, resulted in a destruction of the visual area and a probable softening of the same. Whether the eating of the yeast may have been a factor, or some toxemia which resulted in an unusual viscosity of the blood, thus encouraging the formation of a thrombus in such a constricted vessel, is simply a suggestion offered for consideration. It is well to bear in mind also that the last attack of migraine, preceding this occurrence of permanent hemianopsia, occurred during the menstrual period, when we know that the viscosity of the blood is naturally raised.

550 Park Avenue.

FURTHER STUDIES ON THE APPLICATION OF OZONE TO THE PURIFICATION OF SWIMMING POOLS.

By WALLACE A. MANHEIMER, Ph.D.,

NEW YORK.

SECRETARY, AMERICAN ASSOCIATION FOR PROMOTING HYGIENE AND PUBLIC BATHS.

The application of ozone to the purification of swimming pool water has been under the writer's observation for the past five years. In a comparison of methods for disinfecting swimming pools[1,2] preliminary results were set forth in tests on drinking water. Subsequently the results of tests performed in a miniature pool were reported.[3]

During the latter part of 1917 a large installation was made for experimental purposes in the Twenty-third Street Municipal Bath, New York City. The details of installation, bacterial data, and cost data were reported in the U. S. Public Health Reports March 1, 1918. A summary of these results in part, follows:

3. Ozone when properly applied to the water of a swimming pool effectively purifies the water. When one part of ozone per million parts of water is used, the result is sterile water. When half part ozone per million parts of water is used, a bacterial reduction of 99.8 per cent. results, except when too great an excess of air is introduced with the ozone.

4. A study of the cost of operation of the ozonator has shown that a current consumption of two (2) kilowatts per day with alternating current, and of four (4) kilowatts per day with direct current, plus 1 cent a day for calcium chloride, represents the total operating cost for a 60,000 gallon pool. This amounts to 11 to 15 cents a day for alternating current (at 5 to 7 cents per kilowatt) and to 21 to 29 cents a day with direct current. The cost of refilling the pool is at least $30. The use of the ozonator decreases the number of times the pool must be emptied to such an extent, that the cost of the installation is soon paid for.

5. The application of ozone to the purification of swimming pools is automatic in control, reliable in action, and inexpensive in application. Accordingly we recommend the consideration of this chemical as a standard procedure in the sanitary control of swimming pools.

An extensive series of tests conducted over a period of three weeks was reported later[4], in order to demonstrate the reliability of the process under the varying conditions which obtain in a large swimming pool. The conclusions resulting from these tests were as follows:

"Ozone is recommended for swimming pool purification because:

"1. It is reliable as a disinfectant.

"2. It is capable of purifying heavily polluted pool water.

"3. It produces no objectionable substances in the water.

"4. It improves the appearance and transparency of the water, permitting a longer continued use of the pool, a consequent reduction in the cost of maintenance and a reduction in the hazard of drowning.

"5. It is inexpensive in application."

Additional reports and tests[5,6] were published confirming the above conclusions.

Tests at U. S. Military Academy, West Point, N. Y.

A large ozone equipment installed in the swimming pool of the U. S. Military Academy at West Point came under the writer's observation during the early part of 1920.* Series of tests were taken and sent to the Research Laboratory of the New York City Department of Health.† A summary of these results follows:

The bacterial counts of the water from the deep end of the pool were comparatively low at all times. The counts after filtration showed a noticeable and dependable reduction. The counts after ozonation were as low as average drinking water counts and B. coli were entirely eliminated.

The ozone plant at West Point has been in operation now for over two years and has given continuous and uninterrupted service. In a personal communication to the writer, Col. Timberlake states, "The system is working satisfactorily and no complaints have been received relative to any defects in this system."

*The writer desires to express his thanks to Col. E. J. Timberlake for his kindness in permitting and assisting in the tests herewith reported.

†These tests were made by the Research Laboratory of the New York City Department of Health through the courtesy of Dr. William H. Park, Director.

Sample from	Total Bacterial Count			Gas Produced in Lactose Broth				B. Coli	Interpretation
	at 37°	at 24°	acid col.	by 10cc	1cc	1/10 cc	1/20 cc	present

after Ozone	11	60	0	0	0	0	0	0cc	clean
Tap water control	10	52	0	0	0	0	0	0cc	clean

TESTS AT CLEVELAND CENTRAL BRANCH, Y. W. C. A.*

An extensive series of tests by the Department of Health of the city of Cleveland were conducted in order to test the efficiency of the ozone disinfecting plant. The tabulated results are herewith reported.

TABULATED RESULTS OF THE BACTERIOLOGICAL EXAMINATION OF THE Y. W. C. A. SWIMMING POOL, MAY 9, 1921.

Sample No.	Source	Day	Number of colonies per c.c. on 1% lactoseagar plates	Gas production in 1% lactose bile		10cc
				1/10cc	1cc	
				%	%	%
13142	Pool	4 25	1440	0	bub.	10
13143	Filter	4 25	75	0	0	100 Anaerobic
13144	Ozon.	4 25	3	0	0	0
13147	Pool	4 26	9280	0	0	bub.
13148	Filter	4 26	1920	0	0	10
13149	Ozon.	4 26	0	0	bub.	10
13157	Pool	4 27	Overgrown	0	0	10
13158	Filter	4 27	275	0	0	10
13159	Ozon	4 27	0	0	0	0
13166	Pool	4 28	Inumerable	0	0	bub.
13167	Filter	4 28	1760	0	0	0
13168	Ozon.	4 28	6	0	0	0
13177	Pool	5 2	1190	0	0	15
13178	Filter	5 2	235	0	0	60
13179	Ozon.	5 2	3	0	0	0
13184	Pool	5 3	Inumerable	0	0	bub
13185	Filter	5 3	1860	0	0	0
13186	Ozon	5 3	4	0	0	0
13193	Pool	5 4	11720	0	50	15
13194	Filter	5 4	4960	0	bub.	35
13195	Ozon.	5 4	1	0	0	0
13197	Pool	5 5	Inumerable	0	0	10
13198	Filter	5 5	8900	0	0	bub
13199	Ozon	5 5	11	0	0	0

In the eight series of tests reported the gross bacterial count after ozonation dropped to 3, 0, 0, 6, 3, 4, 1, and 11. *B. Coli* were entirely eliminated.

A similar installation was made in the Lincoln High School, Lincoln, Neb. No copies of recent tests were available at this time. Dr. H. H. Waite, State Bacteriologist, however, in a personal communication, stated, "After the installation of the ozone equipment I made a number of tests to determine its efficiency and found that it was accomplishing all that had been claimed for it. The number of bacteria in the pool was low and the colon bacillus was entirely eliminated."

The Twenty-third Street Bath, originally installed as an experimental plant, has with a few modifications been retained as the permanent apparatus for disinfecting the pool. After a period of nearly four years this plant continues to operate satisfactorily both from the points of view of its bacteriocidal efficiency and its control from an engineering and practical standpoint.*

Conclusion.—The reports of the writer as well as those of several other investigators have shown that the application of ozone to the purification of swimming pools is satisfactory from the practical engineering, and sanitary standpoints.

*The writer is indebted to the City Bacteriologist, Cleveland, Ohio, for the extensive series of tests herewith reported.

1776 WEEKS AVENUE.

QUINO-FORMOL SOLUTION IN THE TREATMENT OF INFECTIONS.†

BY JAMES T. PILCHER, M.D.,

BROOKLYN, N. Y.

THE formation of any new procedure or agent must have a *raison d'être* for its conception. The mechanico-chemical solution which I wish to discuss was primarily conceived during the height of the Chateau Thierry push, owing to the obvious ineffectiveness of Dakin's solution in the treatment of gas gangrene cases with which our wards were filled, and which at that time were subjected to amputations as the only means of saving life. The reason for failure is easily appreciated when one considers the basic pathology of the condition, in that a toxic fluid is first developed which spreads longitudinally along a muscle fiber, between it and the interstitial tissue, killing off the former as it advances, and that it is only after the death of the fiber itself takes place that the anaerobic bacteria invade it acting merely as saprophytes, catalyzing the sugar contents with the consequent formation of gas. The treatment indicated then, appeared to us to be one which would deplete the muscle sheaths of their imprisoned toxic fluid, and sterilize the wound surfaces at the same time.

The use of any solution presupposes the primary employment of the most thorough surgical procedures, and should be used as an adjuvant in the treatment and not allowed to be considered in the rôle of the principal agent—such solutions are not "cure-alls" and must in all instances be used with judgment.

The mechanical problem had apparently been met previously by Colonel Wright in the use of an hypertonic salt solution, although its continued use so changed the local physiological and chemical reactions as to render its ultimate effects harmful. The reason was that the 5 per cent. solution employed was too strong. It undoubtedly does act as a very effective lymphagogue. Its beneficial

*From a communication of Col. Frank H. Hines, Superintendent of Public Buildings, New York City.

†Read before the Alumni of the Mayo Clinic, Rochester, Minn., May, 1921.

action is particularly marked and grossly noticeable where the tissues are lymphbound, infiltrated, and sloughing. It further inhibits protein coagulation and thus prevents the sealing of the wound surfaces. Thus not only is the infected tissue depleted of its toxic fluid, but the spent lymph and inhibited phagocytes are drawn out into the wound and replaced by lymph in which the bacilli present become susceptible to phagocytosis. Again this strong solution caused edematous and unhealthy granulations. The salt solution however does not appear to act as a real germicide. This is to be accomplished in two ways, namely, by bringing active leucocytes to the wound surface or by introducing into the wound some active germicidal agent. The former we accomplished by using a much weaker salt solution and the latter by adding to it a modification of Major Taylor's solution and adding formol and thymol.

The antiseptic problem had been attacked by many methods. Major Taylor evolved a solution of quinine and acetic acid which did not appear to have the irritating properties of other solutions in current use and which was apparently fairly effective. It was thought therefore that by modifying and combining these two formulæ that we would have a basis upon which to work in order to more correctly meet the problem. The hypertonic salt solution was reduced to 1¾ per cent., hydrochloric acid was substituted to put the quinine into solution, and formol and thymol dissolved in alcohol added, not only because of their antiseptic action but because they also very definitely prevented muscular disintegration and materially reduced the presence of the essential media for further bacterial growth.

Our hypotheses were apparently justified by the immediate decrease in the number of amputations, following the use of this quino-formol solution. They indeed became so infrequent as to cause remark. Certainly a great many useful limbs were saved which otherwise unquestionably would have been sacrificed.

The formula eventually found to give the best results consists of

Quinine sulphate	1 gm.
Hydrochloric acid	.50 c.c.
Glacial acetic acid (99 per cent.)	5.00 c.c.
Sodium chloride	17.50 gm.
Formol (40 per cent.)	1.00 c.c.
Thymol	.25 gm.
Alcohol (90 per cent.)	15.00 c.c.
Aqua q.s. ad.	1 liter

It is used exactly as Dakin's solution is employed.

The solution is absolutely unirritating to the skin and mucous membranes. It is stable and capable of concentration. The strength of any of its constituents may be increased or diminished at will, without impairing the action of the other ingredients. It is very easily prepared and is not expensive.

In a preliminary report (*Annals of Surgery*, Nov. 1918) is to be found a detailed account of the character of wounds treated and the results obtained in military hospital work in France.

Since returning to civil practice it has been used by me with the most pleasing results in the treatment of a great many conditions. Stone reports that its use in a large series of empyemas has given better results than he was able to obtain in controls on which Dakin's solutions was used. Several of the Brooklyn Hospitals use it in the majority of their infected wounds. The nose and throat men prefer it, particularly in sinus work, to any of the irrigating solutions previously used. In carbuncles, impetigo and furunculosis its action is most satisfactory, and in all instances of lymphadenitis, cellulitis and phlebitis in which it has been employed the beneficial results have been almost immediate. In such cases one uses a continuous wet dressing of quino-formol, which is most simply applied by laying Carrel tubes over a single layer of gauze next to the skin and then covering them over by more gauze.

Captain Fauntleroy, U. S. N., reports that it has proven of the utmost service in the treatment of very extensive burns, with large areas of sloughs, such as occur in severe scalds in which class of cases he has had an extraordinary experience.

There is nothing which gives better results in the treatment of compound fractures, indeed we have closed two widely opened knee joints, primarily full of filth, after two days preliminary treatment with this solution. It makes an ideal immediate treatment of a mangled, infected hand or limb resulting from industrial or railroad accident, and, being a stable solution, it may always be kept ready at hand in a first aid armamentarium.

These observations are therefore offered for your confirmation and with the hope that in its use may be found a lessening of some of the tedium which so frequently attends the treatment of infective processes.

REFORM OR FANATICISM?

By LUCIUS FELIX HERZ, Ph.B., M.D.,

NEW YORK.

Within recent years, we have been deluged with laws intending to improve the human race, and while good in theory, are often worse than no laws, in actual practice,—because those who wish to break them chafe at the restrictions imposed, and generally break them. In all cases, education, and proper exercise of will power would be far more effective than such laws. The three fields in which these laws have been passed are sexual morality, drug addiction and alcoholism. In all three cases, the problem is far from solved in spite of all the laws we have passed.

In the case of sexual matters, we have wiped out the "red light" districts. We have abolished the brothels. We have stopped soliciting upon the streets. Have we wiped out venereal disease? Most emphatically not. The clandestine prostitute has been with us since history began, and will continue to be with us until we are considerably more advanced in civilization. Education in regard to sex hygiene is a long step forward. Suppression of books on sexual topics,—when they are written in a clean, scientific manner, without any ulterior motive, and with the real object of enlightenment and sparing marital unhappiness,—is a long step backward. It brings

us back to the middle ages. Birth control should be permitted, as large families are unfair to both the mother and the children, and neither would be in fit physical condition to be a true asset to the race. However, disinclination to have any children at all should be vigorously condemned, and by proper education, this undesirable feature should be eliminated. Our reformers of the type of Anthony Comstock, who receive erotic sensations when gazing at pictures of the Venus de Milo, are sexual perverts, pure and simple,—more simple than pure, and should be placed where they can do no harm, rather than making them arbiters of our morals.

In the field of drug addiction, the Harrison Act is excellent in theory, while in practice it leaves much to be desired. A physician who is conscientiously treating a drug addict, with the earnest desire to cure him, may be convicted by a jury of laymen of practising in bad faith, and may be sent to jail. The majority of physicians have been so terrorized by court decisions, and the opinions of reformers within our own profession, who attempt to tell us the correct way to practise medicine, that the greater part of the medical profession will not treat addicts at all. As a result, most addicts receive unlimited supplies from peddlers, and go their own way, drifting from bad to worse. The excuse that the reformers give is that drug addiction cannot be treated satisfactorily except in hospitals. Then, they calmly admit that those treated in hospitals generally have relapses! If drug addicts are to be treated solely in hospitals, let us provide enough hospitals for them, or keep quiet. If every hospital in the country would turn out all its other patients, and accept nothing but drug addicts, we would still have to look around for more places to put them. What are we going to do? Is it not better to use a less effective treatment, but one that cures a definite percentage of cases, than to leave them entirely to their own devices as we are now doing? The majority of cases are not cured by either institutional or ambulatory treatment. However, those possessing sufficient will power can be cured by either method. Gradual reduction, combined with supportive measures, is a recognized method of treatment, and should be permitted. A drug addict is usually of a subnormal type, bordering upon insanity, and hence extremely difficult to cure. But why destroy a method of treatment, when we have not the means or facilities to provide something better?

The drug addict's clinic that had been tried in New York City was unsuccessful for several reasons. In the first place the clinic was conducted by State Commissioners, of whom only one was a physician, and the rest politicians. They got out beautiful sets of statistics, but accomplished nothing of practical value. They were unable to eliminate the peddler, and peddlers were present within a few yards of the clinic ready to supply addicts with more than their allotted dose. Those who took institutional treatment were forced to wear prison garb and were treated as prisoners, even though they had committed no crime. As a result, their morale was poor, and they easily fell prey to the ubiquitous peddler, ready to meet them upon the dock, as soon as they were discharged. The social service part of the institution was entirely neglected.

If our state narcotic commission had been composed of four physicians and one lawyer, probably something constructive would have been accomplished. There has been less progress in the field of narcotic addiction than in any other branch of medicine. Considerable research is indicated. Chemical blood analyses, basal metabolism, studies of shock upon sudden withdrawal, and a careful comparison of the several institutional methods of treatment are all indicated, and their results checked against a number of patients given the ambulatory treatment, in an institution, so as to guard against deception. We will then have a working basis, can standardize our methods, and know definitely the percentage of cures in institutional as compared to ambulatory cases. If the institutional method offers a vastly larger number of actual cures, let us gradually adopt that method, as soon as we can get the necessary number of institutions. There will be, of course, a vast number of institutions required. In the meantime, the other cases must be taken care of in some way, and let us give them the ambulatory treatment, under close supervision. Give them identification cards, force them to be registered, photograph them, even finger-print them, and make it impossible for them to obtain doses from more than one doctor. Give all peddlers heavy jail sentences. Insist that physicians and druggists act in good faith—that is actually try to cure the addict by a reduction of the dose, and that druggists take pains to see that no deception upon the part of the addict, such as getting it for a friend, takes place. I am sure we would obtain encouraging results.

Recently there appeared an article in one of our leading medical journals by a physician who is a member of the narcotic control committee of our State Medical Society. He strongly advocates institutional methods, as he has a right to do. He attempts to back his arguments in favor of immediate complete withdrawal by a statement of a convicted felon, not an addict, who states that drug addicts do not suffer when complete withdrawal is practised. Anybody who has made even a superficial study of this type of case, knows that this is untrue, that they do suffer, and suffer cruelly. They have abdominal cramps, pains in the back and legs, diarrhea, vomiting, the skin breaks out in in a cold sweat, the entire body trembles, they frequently faint, and a few cases of actual death have occurred. The addict is in such distress of mind and body that he would even commit a crime, although it be his first one, in order to obtain his supply of drug. Shall we as scientific men accept the word of a convicted felon with no medical training, or shall we accept the word of Sir William Osler, who states: "The sufferings of the patients are usually very great, more particularly the abdominal pains, sometimes nausea and vomiting, and the distressing restlessness." Osler, by the way, advocates gradual withdrawal. The physician who wrote the article that I object to has every right to his own opinion.

He has, however, no right to tell the rest of his profession that his is the only method they should use, while also admitting that after his method the majority have relapses. Furthermore, he has no right to slur those members of our profession that try to cure addicts by methods different from his own, unless he can prove their method valueless. His *ipse dixit* does not suffice. I do not speak from personal motives, as I no longer treat drug addicts. Not that they do not need treatment, or that I have not the right to treat them, but because the "Pussy-foot Johnsons" of the medical profession have so succeeded in terrorizing their brother practitioners that it is not considered "respectable" to treat these unfortunate patients, and a physician, who from humanitarian motives treats them, frequently has his motives misconstrued, and is sent to jail by twelve laymen, misled by the eloquence of another layman—the prosecuting attorney. When I did treat addicts it was not for the money—nine times out of ten I treated them free and sometimes I actually lent them money. Our friend (?) who wrote the article before referred to is trying to insinuate that all physicians who treat addicts are human vultures and that they are treating them only to extort large fees and know they are not helping them. This is a vile slander against a noble profession.

I know physicians who are practising medicine without ever prescribing narcotics or dispensing them. They do so, not because they never need to, but in order to avoid the amount of keeping of records entailed, and because they do not even want a faint suspicion of prescribing for addicts on account of the odium attached to it. Cases of painful incurable carcinoma, they refuse to treat. That is carrying circumspection to extremes, but that is one of the results when an entire noble profession is treated with suspicion. Some of our would-be reformers would even pass laws prohibiting the prescribing of narcotics in cases of true pain. That law may still come. More surprising things than that have happened.

In regard to alcohol, it was perfectly justifiable to abolish the saloon. It was also advisable to stop strong liquors, because a certain percentage of our population abused them. It was not justifiable to stop beer and light wines. Drunkenness is a curse. The indulgence in moderation of slightly alcoholic beverages, is not only harmless, but often beneficial. Alcohol is a protein sparer and a preventer of tissue waste. It is therefore indicated in many fevers and many wasting diseases. Beer is a harmless beverage, a digestant, and a true food. It is rich in carbohydrates, dextrins, and also vitamines from yeast, besides being a stomachic on account of its malt and hops. Its pleasant taste stimulates the gastric juice and aids digestion. Williams recommends it as a galactagogue. Furthermore, it is our most harmless soporific. In cases where beer is ineffective ale or stout will rarely fail. It is entirely devoid of depression the next morning, such as all other soporifics and sedatives, even bromides, give. By eliminating its use we are forced against our wishes to prescribe more harmful medicaments. I see that our newly elected Chief Justice of the Supreme Court, William Howard Taft, at one time advocated the use of beer and light wines. I hope he has had no reason to change his mind.

As to reformers, the professional reformer is generally a paid propagandist, who earns his living by lecturing upon the subject. Backing him are our narrow-minded extremists, who would give us Sunday Blue laws, regulate the dress of women, stop prize fights, etc. I would suggest that all reformers be first psychoanalyzed. We will then discover what particular disappointment in their own lives determined them to destroy all joy in the life of others. After a proper classification of these human neoplasms has been made I would suggest that they be sentenced to spend the rest of their life in a place where all agreed with their views—Zion City, for instance, having no drinking, no smoking; women wearing dresses trailing the ground, etc. Not seeing any evil left in life, these reformers would soon find no more joy in trying to destroy evil, and so as their mainstay in life, publicity, would be stopped, they would soon grieve themselves to death and would die forgotten and unmourned.

SENSITIZATION TO FOWL PROTEIN MISINTERPRETED AS OF MENTAL AND NERVOUS ORIGIN.

BY JAMES L. TRACY, M.D.,

TOLEDO, OHIO.

THIS paper aims to record data that will be helpfully diagnostic of the condition of sensitization to fowl, that were gathered from a mistake in diagnosis. Singularly enough, scientific conclusions are reached only through the analyses of mistakes. While many diseases may be diagnosed by a single glance at the patient; and while a like glance at the charted temperature, pulse, respiration, and blood-pressure is sufficient for the diagnosis of other diseases, the scientific fact remains that such skill has been obtained at the price of many miscalculations.

The process of ferreting out data of real diagnostic worth, from anomalous or not well understood disease conditions, is bound to be time consuming. No individual case contributes very much. Of course, too, disease conditions may be anomalous or regular, depending upon whether the type of medical skill employed in making the examination be of narrow, or of broad observation. One grade of skill has not yet formulated data, while the other has; one is making diagnostic mistakes in the present, the other has made them in the past. Other than in the vague statement that emanations from fowl may produce asthmatic conditions, I do not know of any data regarding human physical effects from sensitization to fowl that are aids to such diagnosis.

Then, given such data, there is the confusing fact that the physical effects from sensitization will vary in different persons, as do the different mental and nervous peculiarities that invite the sensitization. There would still remain the problem of properly classifying the individual patient with the corresponding type of sensitization so that to publish the data in one case, as is done here, may not

be of great help in diagnosis in any other one case. But to record the different sensitization effects, as they show up in people of different temperaments, may after a while work out a composite picture of sensitization to fowl protein that will be of diagnostic value. The following is the report of the case:

Manifestly to know all about the personal history of the patient is of prime importance. In this case, however, the clue given by a long acquaintance with the patient, a man, actually contributed, as was seemingly demonstrated later, to the covering up of the real source and cause of the disease conditions. I have known him all his life. There is nothing contributory in his personal habits, except possibly the fact that he chews tobacco and smokes two or three cigars a day.

He is 32 years old, 6 feet tall, and weighs 125 lbs. He is a telephone operator, receiving police messages. For two years he has been working night tricks from 11 P. M. to 7 A. M. He thinks the nature of the telephone messages makes him nervous. He has had attacks of follicular tonsillitis (submerged tonsils) several times a year; sometimes bronchitis sets up, but seldom lasting more than a week.

He was married seven years ago. I take it that all physicians have noted the change in facial expression of a young man when his wife has become pregnant! The expression is hard to define, but added responsibility, thoughtfulness, ageing, etc., are shown in the face. This change of expression was very noticeable during his wife's first pregnancy, increased in the second, and very marked in the third pregnancy. Once only during the last pregnancy, and that in the early part of it, did he come to me about himself. But every month or so he consulted about his wife, at which times his facial expression and evident mental perturbation were matters of interest to me. Normally, the man is easily excited, easily angered, but the excitement and anger soon pass.

The Functional Disturbances.—A month before the expected confinement, he came to me about his own condition. As he put it, "He came because of shortness of breath." In coming he had walked a half square. Standing, respiration was 60 a minute. Pulse 140. Reclining, respiration 50, pulse 120. Inspiration and expiration were normal in rhythm. Pulse was regular. Temperature was 96° F. at 9 A. M.; blood pressure 96 and 58. Auscultation detected no râles in any part of the lungs. The very thin chest walls made critical examination of respiratory sounds easy. There was a vesicular murmur over every part of both lungs; but the murmur was lessened, and gave the impression that aeration was increased. Possibly this increased aeration resembled the vesicular murmur in asthma, though there was entire absence of the bronchial sounds of asthma. Respiration was easy, free, regular, and satisfying as far as it went. There was no pulmonary spasm, hence there was not the air hunger as in asthma. Apparently there was no bronchial congestion. The action of the diaphragm was not increased. About two spoken syllables to a respiration were as much as the patient could voice. The act of talking would frequently cause coughing, which was violent and lasted for a half minute, but without expectoration. The quality of the percussion note was normal, but everywhere increased. The intercostal spaces bulged slightly upon inspiration, while vocal and tactile fremitus were lessened.

The heart sounds were normal, with no heart enlargement or displacement. Heart action regular. There was no edema or cyanosis, except that the tonsils and fauces seemed darker than normal. The body surface was pale, but the lips were of a healthy color. Patient had been noticing frequent periods of shortness of breath upon slight exertion for a long time. He thought he might have noticed difficulty in breathing for the past seven months, but as he was principally troubled when going upstairs and when walking fast, he had not paid much attention to it. He apparently had had many coughing spells during that time. I judged that the coughing spells reported had resembled the attacks I was witnessing as he talked to me. I was completely misled regarding the nature of these coughing spells.

As I had never seen any combination of symptoms such as his trouble presented, I diagnosed his condition as a bizarre psychosis production; and thought he would get well after his wife's confinement, and so told him!

Subsequent Course of the Trouble.—Two months after my first examination, and one month after the confinement was over, he was examined by a throat specialist. Nothing more was found by the examination than has been mentioned above, except that all the conditions were a little more aggravated, and a nasal condition existed that resembled atrophic rhinitis. The specialist agreed with me that it was possible that the trouble had originated in the tonsils, and advised their removal as soon as the man could be put in condition safe for operation. He prescribed for the nasal trouble, ordered the man to bed, and recommended morphine to quiet and relax the nervous tension. Digitalis and strychnine were also given. After a few days the patient became quiet and did little else but eat and sleep. He was soon taking three times as much food as before going to bed. Evidently he was assimilating the food. Too, he was making up for much lost sleep.

The nasal douches ordered by the specialist brought away, particularly in the morning, a great many crusts and much mucopus. He coughed considerably during the day, and upon awakening in the morning would be seized with an attack which would last incessantly for nearly two hours. A half dram of sputum showed only pavement and a few columnar epithelial cells. Temperature taken every three hours for a week never showed higher than 97° F.

After ten days' rest in bed pulse was 108 and respiration 36 when he was not talking and was quiet. The lung condition had not changed. Shortly after this the temperature and blood pressure began to very slowly rise, and at the end of the third week in bed the temperature remained at 98°, and blood pressure was 100. The nasal trouble was greatly improved. Coughing in the morning had entirely stopped and in every way he was very much better. Respiration, though, remained at 36. Then one day, while auscultating the chest, I heard the air enter the lung normally, while the patient was making an effort to take a deep breath. Respiration immediately came down to 20 and pulse to 84.

For recreation, this man sported with homing pigeons. He was around the house for a few days, and then walked out and into the pigeon house. Presently he came back coughing, and coughed incessantly for two hours. During this time there was a profuse discharge from the nostrils, and he expectorated large quantities of mucus. Temperature soon went to 102.5°.

Then! I obtained from the wife the information that every day since he had first had the pigeons—nearly a year—he had had a coughing spell every time he went into the pigeon house. Sometimes he was coughing most of the time, because he was often with the birds. The wife had often thought that the birds were in some way responsible for the attacks of coughing. The man's interest in the sport, however, would not let him entertain the idea. He told me that some of the birds had died of what he thought was tuberculosis, and that others had had "canker" (Roup), which he had treated. No specific infection, however, could be found in the patient.

In about ten days he had recovered from the condition and was again as well as when he went into the pigeon house. Then disregarding advice, because of his infatuation for his hobby, he went, but only looked at the pigeons. In a half hour he was again coughing as violently as before. After four or five days in bed and as many more sitting around the house, he was back again to normal. It took one more attack to convince the man!

Now, a diagnosis so tediously worked out legitimately raises the question as to whether or not the refinements of group practice, including basal metabolism and other tests, would have short-cutted to a diagnosis?

Data Diagnostic of Fowl Sensitization.—1. Sensitization to fowl is dependent upon a preexisting cell receptivity to fowl emanation.

2. The presence in the patient of mental and nervous peculiarities should suggest lack of cell integrity.

3. Absence of reasonable pathological foci as a cause for existing functional derangements points toward inept nerve cell condition.

4. The nerve cell sensitized to fowl works out the inhibition of the terminal distribution of the autonomic nervous system.

5. Frequent infection in some way ultimately brings about constant subnormal temperature, subnormal blood pressure, with the functional subnormal trend further showing up in the rapid work of the heart trying to make up for the air stagnation in the vesicles.

6. Sensitization to fowl differentiates itself from the asthmatic group in that (a) it is not a seasonal or periodic disease. (b) It is febrile in its commencement. (c) Nasal passages and large bronchi secrete profusely. (d) Bronchial secretion is easily expelled. (e) It is entirely free from bronchial spasm. (f) Single infection tends to recovery in ten days. (g) It leaves no structural change. (h) Complete recovery of all functions occurs after daily exposures extending over many months.

West Woodruff Avenue and School Place.

EDUCATION IN ITS RELATION TO THE USE OF MEDICAL KNOWLEDGE.

By H. S. BENNETT, A.B., M.D.,

WASHINGTON, D. C.

Is the term "Medical Education" a misnomer? There has been much written about and around the subject of medical education regarding the prerequisites for the general practice of medicine. No small amount of this discussion in print has centered in the question of medical economics as related to (1) the needs of local communities and (2) the ambition of aspirants to the medical field; and comparatively little stress has been laid upon the deeper need—unrecognized oftentimes—of the physiologic body as the dwelling of the individual consciousness. All of the varied forms of expression and the opinions advanced have been of value, as honest opinions must ever be, in showing the trend of thought and in acquainting us all at large with the composite individuality in our midst; but the cumulative effect upon my own mind has been to make me feel that licensure and not maximum efficiency has been regarded as the goal. If this is a fact, it is of course a grave error.

But what is the essential primary need for the attainment of maximum efficiency along any line of higher endeavor? Assuredly it is, first, the best material and, second, the ability to use that material to the best advantage. Obviously, with regard to the first, the material presented is largely the result of an autogenic conception of fitness on the part of the individual—the instances in which outside influences are brought to bear are comparatively so few as to be negligible. Time and attempted training will, to the conscientious aspirant, prove to be a selective process in which elimination will eventually contribute to other fields of endeavor and leave those to whom the second essential need is applicable. It is in the fulfilling of the requirements of this second need that I believe we find the *sine qua non* of professional efficiency upon which the best medical knowledge and training in the use of that knowledge will alone produce the desired end.

Up to this point we have not reached the medical school except as a distinct point of magnetic attraction but have to do solely with the individual and his development, morally, intellectually, and spiritually. In other words, we are ready to educate, *i.e.* to awaken, to develop, and to activate those genetic qualities and abilities which are already existent and which comprise the sum-total of all education except that obtained in the school of experience which is never closed. Quite distinct from, although allied to education is the acquirement of knowledge, and to furnish this is the function of the professional school.

This is true of all of the so-called learned professions, but of none is it true to such an extent or so dependent upon the undeviating order of its attainment as of the medical profession. In the practice of our profession we are dealing with not merely a finely adjusted and highly sensitive mechanism called the organic body, but with that triune entity called man in whom the will to do and to be is coexistent with his somatic elements and is correlated with, and dominated by, that supreme power under which the sentient man becomes the living being capable of reproducing his kind in the likeness of his Creator. We have to do with this triune being made further complex by association with others of his kind, each having his individuality with certain points of correspondence and contact which modify or accentuate, stimulate or retard the process that we see reflected in the end results known as "cases." In fine, we have a super-complex of direct and referred, related and interrelated psychic and somatic manifestations which, if once in disequilibrium, no amount of acquired knowledge or scientific training of a strictly medical nature can properly restore to its even normal balance.

Just as the "greatest study of mankind is man," so the greatest and essential study of man is himself, which alone can enable him to know and wisely treat his fellow man. There is inherent in man a modicum of mental equipment which is the possession of everyone and added to this there is, in individual instances, a variant of plus ability all of which, through the individual intellect, may become subjective knowledge, but I believe that every thinking mind will bear me out in the assertion that no knowledge may be claimed as a possession until the intellectual processes have become able to demonstrate it and to utilize its worth. In this respect, and in this only, knowledge is power—a power without which the mind is little more than a warehouse with doors locked, but with which it is enabled to illuminate the minds of others and to read thereby the story of their needs.

The correlative instincts of mankind—if I may use that term as applicable to psychic phases—trend ever each toward its known or unknown

counterpart, and toward the recognition and correct interpretation of these instincts the mind of the physician applies itself. He must be able not only to interpret to himself these instincts and their various trends but he should be able so to project his own mind into that of his patient as to draw out and interpret to him those feelings, thoughts and influences which are inducing either expression or repression with a maleficient effect.

To-day more than ever before within the memory of man we have to deal with the emotional complex—a condition in the train of which there follows an ever increasing number of symptoms which to the average practitioner point unmistakably to localized disease of either a functional or an organic nature, and a diagnosis is rendered and treatment initiated accordingly with the well known result of a long-continued attendance upon a series of varied recurrences following upon new developments accompanied by a resistance that falls in direct ratio to the length of such treatment. The patient is kept continually in hope by the temporary relief afforded and gladly pays for what he believes are slow but sure steps toward the goal of health. To the physician it is a lucrative procedure and is carried out in all sincerity of purpose and belief in the warrant and wisdom of his chosen course—for, bear in mind, I am not accusing any one of the medical profession of intentionally protracted treatment solely for his own monetary gain. In this very fact, however, lies the reason for a reform which shall, by diminishing ignorance on the part of the profession, increase the benefit to the patient and hasten his restoration to health.

But this ignorance, which might more properly be termed inability, cannot be diminished to the extent required by the further acquisition of technical knowledge; it represents an ignorance of the autogenetic in the physician as well as in his patient and an inability to utilize his full capabilities because of an ignorance of their existence. If Hahnemann's dictum, "Similia Similibus Curantur," is true as applied to the uses of Materia Medica, it is certainly true as applied to the correlated instincts, emotions, and tendencies of mankind which are intangible and undiscoverable save through a mutuality of understanding. How often have we heard the remark: "He understands me and helps me so much." There is truth and sanity in that statement, and the "help" comes not simply because he "understands" but because, by reason of that understanding, he has been able to neutralize the mental toxins of unrest and disproportion and thereby stabilize and clarify the perspective of life. After that we have a clear picture, be the condition simple or complex. The physician should be able to produce a sympathetic antidote for primary emotional ills and thus prepare and cultivate a physiological medium for the germination, growth, and ultimate fruitage of proper medical therapeusis.

Taken by and large, there is and can be no substitute for the preliminary general education which a first grade university offers to the prospective medical student, no matter how broad, thorough, or highly specialized the course of the medical college may be. The process of individual mental development, to be effective, must come at a period of life when the student is too young safely to enter a medical college; it should be among surroundings which are free from any restrictive influence, either real or implied, that would tend to build up a mental bias and hamper the outgrowth of a selective choice of avocation; and it should be under influences which would develop and solidify those immutable moral principles of life and conduct without which no one should be permitted to enter upon a course of training for the medical profession.

There is too low an estimate placed to-day upon the value of the man. The proportionate appraised value of his technical equipment to his moral worth is not a safe one. While there should be no limit placed upon professional efficiency, the high calling of the physician is such as to place within his free control all that is most sacred in life and most holy in conception, and demands the absolute subservience of personal ends to the highest type of Christian altruism. The time has come when it is eminently in order to renew our allegiance to those fundamental principles upon which rests the honor of the medical profession, and to do this without making every effort to safeguard it for the coming generations would be to shirk our responsibility and ultimately to defeat our purpose.

4127 Harrison Street, N.W.

Medicolegal Notes.

Liability of Charitable Hospitals as Regards Negligence of Servants.—In an action against a charitable hospital for injuries alleged to be due to the negligence of a nurse employed by the hospital, it appeared that the patient was a pay patient, who did not know that the hospital was a charitable institution, and who provided her own doctor. In an exhaustive opinion, in which it reviews the prior cases on the question of the liability of charitable hospitals for negligent injuries inflicted by their servants, the Supreme Court of Appeals of Virginia arrives at the conclusion, two judges dissenting, that the duty which the hospital owed to the patient in this case was the exercise of due care in the selection and retention of the nurse in charge of the patient; and that, negligence in respect of this duty not having been shown, no error was committed by the trial court in sustaining the defendant's demurrer to the plaintiff's evidence.—Weston v. Hospital of St. Vincent of Paul (Va.), 107 S. E., 785.

Error in Admission of Evidence Held Invited by Complaining Party.—In a personal injury case the petition alleged that the plaintiff's injuries were a fractured skull and concussion of the brain, and that as a result her entire nervous system had been seriously and permanently deranged, her vision, memory, and hearing had been impaired, etc. After a doctor had testified that he had seen the plaintiff about three weeks prior to the date of the trial, and made an examination of her, at which time he found that all the contusions and bruises had been cleared up, the defendant's counsel then asked the following question: "And, objectively, did you find anything objectively?" The defendant's counsel, after an answer had been given, insisted that the doctor state further, and the doctor testified that the plaintiff did not seem to have the full degree of intelligence that she ought to have. It was held that if the admission of this answer was error, it was invited by the defendant's counsel, who therefore could not complain.—Albert v. United Rys. Co. (Mo. App.), 232 S. W., 793.

SUDDEN DEATH IN STATUS THYMICO-LYMPHATICUS.

THE matured opinion of those who interest themselves in this subject is that the causes of sudden death in this state represent a congeries of restricted types rather than a single autonomous condition. It is conceivable that if the thymus has attained certain dimensions it may exert compression on the trachea and cause suffocation or chronic dyspnea according to the degree of pressure. A much smaller thymus could produce the same result by acting as a wedge between the sternum and trachea. In such cases there would have to be shown flattening of the trachea. But in some newborn infants who have evidently succumbed to suffocation the flattened trachea could not have been due to the pressure of the thymus, which was normal in size. The mere coincidence of enlarged or persistent thymus with asthma can hardly be due to compression, but to some other factor. The symptoms may be very mild and have no suggestion of obstruction.

Ryser, who attempts to throw new light on this subject in an article in the *Schweizerische medizinische Wochenschrift* for June 16, 1921, li, 24, says there is a syndrome of thymus pressure which comprises other organs besides the trachea in which the heart and vessels and nerve trunks may be involved. Compression of the important vessels and nerves in this area may presumably disturb the circulatory and respiratory rhythm and cause dyspnea and even possibly death by vagus compression. In cases of sudden thymic death so called, in the absence of symptoms of compression an exhaustion of the supply of adrenalin has been accused. It is known that in status lymphaticus the chromaffin system is often underdeveloped and to explain this coincidence it has been thought that the chromaffin and lymphatic systems are antagonists. Hypoplasia of the chromaffin organs is associated with general hypoplasia and functional insufficiency and many sudden deaths in the water, during mountain climbing, etc., have been attributed to exhaustion of adrenalin. In such cases the presence of hyperplasia of the lymphatic system is to be regarded not as a cause of death but as a mere index of the subject's physical constitution. In certain of these cases of sudden death the only find mentioned at autopsy is destruction of the adrenals. Death during chloroform narcosis may be due to the same mechanism, and in fatal preoperative fright in the absence of chloroform, adrenalin exhaustion has also been accused. Another endocrine factor accused in sudden death is hyperthymization, from hypersecretion of the often greatly enlarged thymus. Thymus extract is said to be a physiological antagonist of adrenalin. The author is no partisan of this view, for which there is only a meagre laboratory foundation. However, one may speak of a general perturbation of the endocrine balance in connection with sudden deaths.
